Atypical periodic paralysis and myalgia
A novel RYR1 phenotype

Abstract

Objective
To characterize the phenotype of patients with symptoms of periodic paralysis (PP) and ryanodine receptor (RYR1) gene mutations.

Methods
Cases with a possible diagnosis of PP but additional clinicopathologic findings previously associated with RYR1-related disorders were referred for a tertiary neuromuscular clinical assessment in which they underwent detailed clinical evaluation, including neurophysiologic assessment, muscle biopsy, and muscle MRI. Genetic analysis with next-generation sequencing and/or targeted Sanger sequencing was performed.

Results
Three cases with episodic muscle paralysis or weakness and additional findings compatible with a RYR1-related myopathy were identified. The McManis test, used in the diagnosis of PP, was positive in 2 of 3 cases. Genetic analysis of known PP genes was negative. RYR1 analysis confirmed likely pathogenic variants in all 3 cases.

Conclusions
RYR1 mutations can cause late-onset atypical PP both with and without associated myopathy. Myalgia and cramps are prominent features. The McManis test may be a useful diagnostic tool to indicate RYR1-associated PP. We propose that clinicopathologic features suggestive of RYR1-related disorders should be sought in genetically undefined PP cases and that RYR1 gene testing be considered in those in whom mutations in SCN4A, CACNA1S, and KCNJ2 have already been excluded.

The skeletal muscle ryanodine receptor (RYR1) gene encodes the principal sarcoplasmic reticulum calcium release channel with a crucial role in excitation-contraction coupling. Mutations in RYR1 are the most common genetic cause of nondystrophic neuromuscular disorders,1,2 associated with myopathy,5 and congenital myopathic manifestations. Here, we report 3 additional myopathic and episodic phenotypes due to mutations in RYR1 and Cav1.1 dysfunction and a continuum between a single patient with a recessive periodic paralysis (PP) have been previously reported in various early-onset congenital myopathies—central core disease,3 multimicroneurogenic disease (MmD),4 centronuclear myopathy,5 and congenital fiber type disproportion6—to the malignant hyperthermia (MH) susceptibility trait. RYR1 mutations may also give rise to episodic neuromuscular manifestations, including exertional myalgia and rhabdomyolysis,7 a late-onset axial myopathy,8,9 and have recently been associated with a novel bleeding disorder due to abnormal smooth muscle cell contractility.10 Episodes of atypical periodic paralysis (PP) have been previously reported in a single patient with a recessive RYR1-related myopathy,11 but it has been unclear whether this phenotype was unique to the reported individual or common across different RYR1 genotypes. The association between RYR1 and PP is not entirely unexpected, considering that dysfunction of Cav1.1, the other key player involved in excitation-contraction coupling and the principal RYR1 interactor, is the most common cause of primary PP. Recently, both dominant and recessive families with a Cav1.1-related myopathy have been described,12 suggesting further phenotypic overlap between RYR1 and Cav1.1 dysfunction and a continuum between myopathic and episodic phenotypes due to mutations in these genes. Here, we report 3 additional RYR1-mutated patients presenting with PP episodes and variable additional myopathic manifestations.

Methods

We examined cases referred with a possible diagnosis of PP but additional clinicopathologic findings previously associated with RYR1-related disorders to the national referral center for skeletal muscle channelopathies in the United Kingdom and to the Swiss Neuromuscular Diseases Unit Center.

Standard protocol approvals, registrations, and patient consents

All procedures were conducted as part of routine clinical care. The study was performed under the ethics guidelines issued by our institution, with written informed consent obtained from all participants for genetic studies.

Genetic analysis for PP genes SCN4A, CACNA1S, and KCNJ2 was performed at the Neurogenetics Unit, National Hospital for Neurology and Neurosurgery as provided by the Channelopathy Highly Specialized National Service for rare disease. Samples underwent next-generation sequencing on an Illumina HiSeq after enrichment with an Illumina custom Nextera Rapid Capture panel (Illumina, Inc, San Diego, CA). For case 2, the library preparation and enrichment were performed with TruSight One kit (Illumina) according to protocol instructions, allowing analysis of a panel of >5,000 genes (including PP genes and RYR1). The library was quantified with the Qubit 2.0 Fluorometer system (Thermo Fisher Scientific, Waltham, MA), and 2 × 250-bp paired-end sequencing was performed on the MiSeq sequencer (Illumina), as well as sequences alignment (Burrows-Wheeler aligner) and variant calling (Genome Analysis Toolkit variant caller). The variants were then analyzed with VariantStudio (Illumina).

Additional targeted RYR1 Sanger sequencing of all cases was performed at the Diagnostic DNA Laboratory at Guy’s Hospital, London.

Results

Case 1

A 54-year-old man was born 7 weeks prematurely. An atrial septal defect was noted at birth and corrected at the age of 5 years. Walking was delayed until the age of 2 years. He was never able to run or to keep up with peers physically because of weakness of his arms and legs. In early childhood, he toed-walked, ultimately requiring Achilles tendon lengthening. Symptoms were effectively stable throughout childhood, but from the age of 20 years, there was slowly progressive proximal weakness.

At the age of 34 years, after a flu-like illness, he complained of a change in symptoms. He reported episodes of sudden severe myalgia followed by profound muscle weakness in either 1 limb or the entire body from the neck down lasting for several hours. Examination demonstrated a waddling gait and pronounced lumbar lordosis and mild dysmorphic features with a long thin face and high arched palate. Mild bilateral ptosis with a complex ophthalmoplegia most marked on upgaze, a typical finding in recessive RYR1-related myopathies, was noted. There was bilateral facial and sternocleidomastoid weakness with additional proximal upper and lower limb weakness. Reflexes were 1+, and there were no sensory abnormalities. Cardiac examination demonstrated atrial fibrillation for which he underwent cardioversion. Because of the change in symptoms, a muscle biopsy was performed. Although core-like structures were seen, they were not felt to be typical of central core disease, a common
RYR1-related myopathy, and no definitive diagnosis was reached (figure 1).

From this point, he continued to complain of episodes of temporary worsening of limb weakness 2 to 3 times a year lasting for several days. He could identify no specific triggers. At the age of 38 years, he presented with an episode of severe neck flexor and bulbar weakness. Over the course of 9 days, his neck flexor weakness improved to baseline. Bulbar function remained impaired, and a percutaneous endoscopic gastrostomy (PEG) tube for feeding was inserted. However, he continued to report fluctuant improvement in his swallow, on some days being entirely reliant on the PEG and on others managing a soft diet. Fourteen months after the PEG insertion, he attended clinic and reported that he no longer used it and consistently managed a normal diet. Videofluoroscopy demonstrated only minor persisting abnormalities, and the PEG was removed at his request.

Over subsequent years, he continued to experience acute attacks of myalgia followed by weakness. When care was transferred to us, he was reinvestigated, including a repeat muscle biopsy at the age of 42 years (figure 2), which on this occasion revealed mild loss of oxidative enzyme activity in the central region of many fibers, but classic central cores were not observed.

Electrophysiologic tests showed myopathic EMG features, normal repetitive stimulation, mildly abnormal jitter, and occasional blocking on single-fiber EMG (including in extensor digitorum communis, biceps, and orbicularis oculi). While indicative of a mild neuromuscular junction transmission defect, this was thought likely to be a secondary phenomenon rather than a primary myasthenic feature. Serologic testing for acetylcholine receptor antibodies and muscle-specific kinase antibodies was negative. The McManis test for PP was positive on 2 separate occasions (53% and 59% decrement in

Figure 1  Histology slides of muscle biopsies taken from case 1 at age (A) 34 and (B) 42 years

(A) Histologic examination of a right quadriceps muscle biopsy performed at age 34 years showed variation in fiber diameter and internalized nuclei with hematoxylin and eosin staining. (B) ATPase histochemistry at pH 4.3 indicated type I fiber predominance with decreased myofibrillar ATPase activity in core-like areas in up to 15% of type I fibers (red arrow). (C) Central absence of staining suggestive of cores was apparent in type I and II fibers in the nicotinamide dinucleotide tetrazolium reductase preparation (black arrows), and central reduction in oxidative enzyme activity was confirmed by succinate dehydrogenase staining (D, black arrow). Scale bar in A represents 100 μm in (A) and (C), 200 μm in (B), and 50 μm in (D).
compound muscle action potential [CMAP] amplitude). MRI demonstrated fatty infiltration of all thigh muscles, in particular the adductor magnus, which was almost completely replaced by fat, with relative sparing of the vastus lateralis, rectus femoris, gracilis, and semitendinosus, a pattern of selective involvement previously associated with RYR1-related myopathies.14,15 There was no family history of similar symptoms. Genetic analysis revealed RYR1 variants Arg109Trp, previously described with MmD and ophthalmoplegia,4,16 a variant of uncertain significance Met485Val,4 and the novel although presumed truncating variant Gln70X. Testing for congenital myasthenia and PP genes was negative. His unaffected mother carried the Gln70X variant. It was not possible to obtain DNA from his father.

Case 2
A 42-year-old Swiss woman presented with intermittent weakness of the limbs lasting from several minutes to 2 days.
Medical history was notable for migraine and 3 caesarean sections. The first episode of flaccid paresis occurred during her first pregnancy at the age of 23 years with a fall from the couch when she could not move her right arm and leg for several minutes, without associated disturbance of cognition or sensory symptoms. Examination at the emergency room after recovery was normal. Brain imaging was not performed because of the pregnancy. Two subsequent EEGs were normal, and no specific diagnosis was made at the time. She had a history of migraine, and we cannot definitively exclude the possibility that this first episode of unilateral weakness was a migraine aura without headache. However, her typical migraine episodes are headache and are distinct from this presentation. Fifteen years later, while driving, she noted weakness of her arms, legs, and trunk severe enough to warrant stopping the car. Weakness recovered slowly after 15 minutes. A similar episode occurred a few months later. Potassium levels and clinical examination when asymptomatic were normal. Subsequently, the frequency of similar episodes with flaccid paresis of her limbs, affecting predominantly the legs and lasting several minutes, increased and they occurred daily, always after resting. No correlation with food intake or fasting was reported. In addition, she complained of painless cramps in her arms and legs muscles, which could become painful if she tried to stretch her muscles. These lasted up to 10 minutes and also occurred during sleep.

A detailed neurologic examination at the age of 42 years revealed no abnormalities. A relatively thin and long face with a small lower jaw was noted, but she was not overtly dysmorphic. On follow-up examination, she presented with flaccid weakness of her right hand lasting for 2 days. Motor and sensory nerve conduction studies, repetitive motor nerve stimulation, and EMG in the limbs and paravertebral muscles performed after recovery from the acute episode were unremarkable. The McManis test was negative. Laboratory testing revealed no thyroid dysfunction; electrolytes and creatine kinase were normal. Muscle biopsy of the tibialis anterior muscle demonstrated variation in fiber size, an increase in internal nuclei, and 1 ring fiber (figure e-1, http://links.lww.com/WNL/A96). A type I fiber predominance was interpreted as normal for the muscle biopsied. Genetic testing for PP genes was negative, but an RYR1 variant Arg1043His was identified. Another amino acid substitution at the same site, Arg1043Cys, previously associated with the MH trait but not functionally tested yet (www.emhg.org), has been described.

### Discussion

We have previously reported a single patient with recessive RYR1-related MmD with additional episodic muscle weakness/paralysis. Here, we have described 3 additional cases (summarized in the table). One was compound heterozygous for RYR1 nonsense and missense mutations and presented with later development of episodic symptoms in the context of a congenital myopathy, similar to our original patient reported by Zhou et al.17 who showed a comparable genotype and phenotype. The other 2 patients had an episodic phenotype without myopathy and were either heterozygous for or compound heterozygous for RYR1 missense mutations (putatively) implicated in the MH trait, suggesting tentative genotype-phenotype correlations. In all cases (including our original case), the onset of episodic muscle paralysis was from early adulthood onward, which is later than the onset typically seen in primary PP. Although there were variable triggers, including exertion or rest after exertion, which is a typical trigger for PP, there was no consistent relationship to food or temperature across all the cases. Myalgia or cramp was a universal feature, indicating overlap with the spectrum of RYR1-related exertional myalgia/rhabdomyolysis, and this, together with the later age at onset, may be a phenotypic clue for future cases.

The McManis test was positive in 2 of 3 of our new cases. We retrospectively reviewed the source data for our previously reported case11 and found that the drop in CMAP amplitude when calculated from the postexercise increment was also >40%, indicating a positive test.
A positive McManis test, to the best of our knowledge, has previously been described only in primary or secondary PP.\textsuperscript{18} Given the direct interaction between the Cav1.1 channel implicated in the majority of cases of hypokalemic PP\textsuperscript{19} and RYR1, it seems plausible that dysfunction of each may produce phenotypic mimics. This is supported by the observation of a profound disturbance of the normal BK channel activity in RYR1-mutated smooth muscle cells\textsuperscript{10} one possibility is via an impairment of mediated membrane repolarization due to one positive McManis test is unclear. On the basis of the recent observation of altered BK channel activity in RYR1-mutated smooth muscle cells,\textsuperscript{10} one possibility is via an impairment of BK channel–mediated membrane repolarization due to altered intracellular calcium homeostasis, but this requires further study.\textsuperscript{10,21,22}

Other atypical PP phenotypes associated with motor neuropathy due to mitochondrial gene mutations have been described,\textsuperscript{23} demonstrating that the clinical symptoms may be seen in non–ion channel genetic disorders. Our data demonstrate that late-onset episodic muscle weakness or paralysis with prominent myalgia and cramps may be a more common RYR1-associated phenotype than the single case we previously reported and may not be limited to a specific genotype. We suggest that cases compound heterozygous for RYR1 nonsense and missense mutations are more likely to have a concomitant early-onset myopathy. The McManis test may be a useful diagnostic tool in these cases, although a negative test does not exclude the possibility of RYR1 involvement.

We propose that clinicopathologic features suggestive of RYR1 disorders should be sought in genetically undefined PP cases and RYR1 gene testing considered in those in whom mutations in SCN4A, CACNA1S, and KCNJ2 have already been excluded.

Study question
What are the phenotypic characteristics of patients with periodic paralysis (PP) symptoms and RYR1 mutations?

Summary answer
These patients can have late-onset atypical PP with or without myopathy and with myalgia and cramps as prominent features.

What is known and what this paper adds
RYR1 mutations are associated with diverse neuromuscular disorders, including 1 reported case of atypical PP. This study describes the phenotypes of 3 more patients with RYR1 mutations and PP episodes.

Participants and setting
This study reports 3 patients with possible PP diagnoses and clinicopathologic findings typically associated with RYR1-related disorders who were referred to UK and Swiss specialist centers.

Design, size, and duration
Medical histories were collected for all 3 patients. These histories included muscle examinations at various ages. Sanger sequencing for RYR1 was performed on patient samples.

Main results and the role of chance
Case 1 was a 54-year-old man who had lifelong muscle weakness. At 34 years old, he experienced worsened symptoms, including sudden severe myalgia. Examinations revealed various neuromuscular abnormalities, including positive results on the McManis test for PP. Case 2 was a 42-year-old woman who had experienced episodic muscle weakness and migraine symptoms since the age of 23 years. A neurologic examination yielded unremarkable results, but the McManis test yielded positive results. All 3 patients carried various RYR1 mutations and reported myalgia and/or muscle cramps.

Bias, confounding, and other reasons for caution
These case reports do not firmly establish a genotype-phenotype relationship or explain the physiologic mechanism by which RYR1 mutations would cause late-onset atypical PP.

Generalizability to other populations
Late-onset atypical PP may be more common in persons with RYR1 mutations than the single previous report suggested.

Study funding/potential competing interests
This study was funded by the UK Department of Health. Some authors report receiving funding from the UK and European Union governments, pharmaceutical companies, and medical research foundations. Some authors report receiving personal compensation from pharmaceutical companies. Go to Neurology.org/N for full disclosures.

A draft of the short-form article was written by M. Dalefield, a writer with Editage, a division of Cactus Communications. The authors of the full-length article and the journal editors edited and approved the final version.
