Introduction

New laser scanning technologies are set to revolutionise the way in which we measure and understand changes in ecosystem structure and function. Forest ecosystems present a particular challenge because of their scale, complexity and structural dynamics. Traditional forestry techniques rely on manual measurement of easy-to-measure characteristics like tree girth and height, along with time-consuming, logistically difficult, and error-prone destructive sampling. Much more detailed and accurate three-dimensional (3d) measurements of forest structure and composition are key to reducing errors in biomass estimates and carbon dynamics and to better understanding the role of forests in global ecosystem and climate change processes. Terrestrial laser scanners (TLS) are now starting to be deployed in forest ecology research and, at the same time, new TLS technologies are being developed to enhance and extend the range of measurement that can be made. These new TLS measurements provide a tantalising glimpse of a completely new way to measure and understand forest structure. It is therefore a good time to take-stock, assess the state-of-the-art, and identify the immediate challenges for continued development of TLS in forest ecology.
This issue of Interface Focus is a collection of papers based on invited presentations at a Royal Society Theo Murphy Scientific Meeting held at the Kavli Royal Society Centre, Chicheley Hall 27-28 February 2017. The meeting was organised by Professor Mark Danson, Dr Mat Disney, Dr Rachel Gaulton and Professor Crystal Schaaf and was attended by around seventy participants representing twelve different countries. In addition to the invited presentations, available as audio recordings at https://royalsociety.org/science-events-and-lectures/2017/02/forested-ecology, a poster session provided an opportunity for further eighteen authors to present and discuss their work with meeting participants.

The planning of the meeting was underpinned initially by the activities of the Terrestrial Laser Scanning International Interest Group (TLSIIG) initiated by Professor Alan Strahler and others, at the SilviLaser meeting in Vancouver in 2012. TLSIIG is an informal network with more than 170 participants with an interest in the ecological applications of TLS (http://tlsiig.edu.bu). The group conducted a TLS inter-comparison experiment in Australia in 2013 and a series of follow-up workshops in the U.K., France, and Finland in 2014 and 2015. In 2015 the group was successful in gaining funding from the U.S. National Science Foundation (NSF) for a Research Coordination Network (RCN) under the leadership of Alan Strahler and Crystal Schaaf, and the RCN now has 70 participants representing 31 institutions and nine countries with the objective of developing new applications of TLS in forest ecology. The Royal Society meeting provided an opportunity for researchers in the RCN and beyond to come together in a highly focussed and interactive environment in order to discuss their research, highlight successes, and identify future challenges in the field. A particular aim of the meeting was to invite a diverse range of researchers from areas such as ecology, functional structural plant modelling, and forest dynamics, to see how new developments in TLS might change their thinking.

The first two papers in this special issue are reviews written by ecologists working with TLS data. Malhi et al. [1] provide an ecological perspective on the challenges of applying TLS to characterise tree form. They outline how the pioneering work of the French botanist Francis Hallé and his 23 models of tree forms is now being extended with TLS data to develop new mechanistic theories of tree growth and development, and to test fundamental theories of metabolic scaling, which have proved extremely difficult to test any other way.

In a second review Orwig et al. [2] outline the potential role of TLS in a wide range of ecological applications, focussed on Harvard Forest, Massachusetts. This famous test site has seen range of new laser scanning devices deployed over the last decade aimed at characterizing forest stand dynamics, in particular in the ForestGEO plot which serves as a model for forest change in New England, including the impacts of the invasive hemlock woody adelgid (Adeleges tsugae). New developments in TLS technology are introduced in the papers by Danson et al. [3] and Li et al. [4] where the concepts and applications of multi-wavelength full-waveform data collection are introduced. To date there are no commercial TLS instruments that provide both full-waveform data and measurements in two or more laser wavelengths. These papers together introduce and evaluate two experimental TLS systems that have been specifically developed to
measure the structural and biophysical characteristics of forest canopies, both focussing on the particular problem of separating TLS point clouds into leaf and wood components.

There follows a series of papers on developing applications of TLS in forest ecology. Disney et al. [5] describe new methods for deriving above ground biomass (AGB) estimates for forest stands using geometric models from which tree volumes are computed. They emphasise the large errors in current allometric equations, particularly in tropical regions, and the critical role for TLS measurements in reducing this uncertainty, as well as providing baseline measurements for forthcoming spaceborne missions to map forest structure. Elsherif et al. [6] take a novel approach to the estimation of leaf water content using TLS data. They deploy two laser scanners with different wavelengths to measure tree leaf water content, merging the point clouds and deriving a normalised difference index (NDI). This is shown to be strongly correlated with water content in both needle-leaved and broad-leaved trees, and so provides quantitative measurements of 3d distribution of leaf water content. Åkerblom et al. [7] use a new approach to insert modelled oak leaves into geometric models of oak trees that have been derived from leaf-off scans recorded in the winter. The reconstructed leaf-on trees are then compared with destructively sampled data as validation. The method has potential applications in better understanding the issues in tree volume estimation with leaf-on TLS data, and for cross-validation of leaf area index estimates derived from TLS.

Several issues relating to the spectral and spatial characteristics of TLS data are addressed in the next series of papers. Kaasalainen et al. [8] demonstrate the importance of incidence angle effects on the intensity measurements recorded by TLS. They use their multi-wavelength TLS instrument to characterise the wavelength-dependence of incidence angle and leaf structure effects on all TLS measurements. These effects may be minimised using ratios of wavelengths that are spectrally close and will important in future systems using multiple wavelengths across the visible and short-wave infrared region. The spatial relationships between the 3d shape of ecological objects, and TLS point clouds is explored in the paper by Paynter et al. [9]. They show that the volume of ecological objects derived from a range of geometric models fitted to TLS point clouds can vary significantly with the object shape characteristics and the model selected, and they argue that generalised quantification of scanning errors can be estimated from the lower error bounds of volumes derived by such fitting. Morsdorf et al. [10] bring some of these ideas together and consider both the extraction of physical information from and semantic labelling of TLS point clouds. They introduce the concept of occlusion mapping that will help in understanding the limitations of data from TLS for forest mapping, compared to UAV-based or other airborne laser scanning systems. This theme is picked up in the final paper in the issue by Roşca et al. [11] who compare UAV-based structure-from-motion aerial photography with TLS to measure top-of-canopy structure in a tropical forest.

Taken together these papers represent a broad perspective of the current research on the rapidly developing applications of TLS in forest ecology. They highlight technical developments that are expanding the range of measurements that can be made, the advances in computer-
based modelling and analysis of TLS data sets, and the new types of information, derived from TLS, which will be shape forest ecology in the future.

We would like to dedicate this issue of the journal to Dr Sandra Brown who died shortly before the meeting was convened. Sandra was a strong supporter of our research, and of the Royal Society meeting, and had planned to attend. A graduate of the University of Nottingham she gained an MSc and PhD in the United States, where she remained for most of her career carrying out pioneering work on the role of forests in the global carbon cycle. The influence of Sandra’s work is seen throughout the research described in this issue of Interface Focus and it is therefore fitting that we remember her here.
