Abstract

An ex vivo, porcine spleen perfusion model was established to study the early events occurring in the spleen prior to the onset of bacterial sepsis, using organs retrieved from animals slaughtered for food production. Porcine spleens were harvested from adult pigs and connected to a normothermic extracorporeal perfusion circuit. A constant perfusion of heparinized blood was performed for 6 hours. After injection of Streptococcus pneumoniae to the circuit serial samples of both blood and spleen biopsies were collected and analyzed. Functionality of the perfused organs was assessed by monitoring the blood-gas parameters, flow rate and filtering capability of the organ. Interestingly, we observed full clearance of bacteria from the blood and an increase in bacterial counts in the spleen. Classical histology and immunohistochemistry on biopsies also confirmed no major damages in the organ architecture and changes in the immune cell distribution, other than the presence of clusters of pneumococci. A time-course study confirmed that each focus of infection derived from the replication of single pneumococcal cells within splenic macrophages. The model proposed – in line with the 3Rs principles – has utility in the replacement of experimental animals in infection research. Murine models are prevalently used to study pneumococcal infections but are often not predictive for humans due to substantial differences in the immune systems of the two species. This model is designed to overcome these limitations, since porcine immunology and splenic architecture in particular, closely resemble those of humans.

1 Introduction

Animal models are still commonly used to study infectious diseases caused by bacterial pathogens. Thousands of animal models have been developed, specifically designed to study a particular type of infection and their cognate pathologies. Rodents are the most commonly used animals due to the low cost and the ease of use but several other animal species have been used as models of bacterial infections (Fink, 2014).

National and international legislation, media and public opinion are encouraging the development of alternative approaches in biomedical research that avoid the use of experimental animals (EU, 2010). New biomedical research funding agencies have emerged in order to guide and support forward-thinking scientists who are putting their efforts to find more ethical alternatives to animal experimentation, and many pharmaceutical companies are now also embracing the principles of 3Rs (Prescott and Lidster, 2017; Fleetwood et al., 2015).

Beyond the important ethical concerns around the use of experimental animals, one of the main limitations of the use of these models is the lack of translatability to humans (Steiniger, 2015; Mestas and Hughes, 2004; Seok et al., 2013). The majority of animal-based pre-clinical research in the field of bacterial infections, particularly in the industrial setting, aims at the development of new antimicrobial compounds and vaccines. However, some of these animal models do not translate to humans and their use resulted in a number of cases in which compounds that showed efficacy in pre-clinical studies, then failed in clinical trials (Mak et al., 2014; Mitka, 2011).

In this study we describe an innovative ex vivo model of infection using local, abattoir-sourced porcine spleens, which allowed the replacement of the use of protected animals. The model has been successfully used in a recent study (Ercoli et al., 2018) and will be extensively described in this article. Autologous, ex vivo perfusion maintains normal physiological parameters, histological characteristics and function for prolonged periods, and allows for a detailed analysis of the organ...
responses to various biochemical and hormonal changes (Imber et al., 2002b; Imber et al., 2002a; Butler et al., 2002; Daniel et al., 2018). Our group has previously developed other ex vivo porcine organ perfusion models to study organ physiology (Chung et al., 2013). The main aim of this model was to study the early stages of bacterial sepsis. Porcine spleen resulted as an ideal choice for this work since pigs have already emerged as relevant biomedical models to study infections (Meurens et al., 2012; Brogaard et al., 2016) and spleen is an organ with a well-defined role in the pathogenesis of invasive bacterial disease (Horan and Colebatch, 1962; Theilacker et al., 2016; Shinefield et al., 1966). Indeed, spleen actively works as a blood filter, trapping the bacteria and killing them during bacteremia and sepsis. Furthermore, porcine spleen more closely resemble the human organ than the murine one, with high numbers of circulating neutrophils, comparable microanatomy and subpopulations of splenic and lymph node macrophages, similar T-cell subpopulations and cytokine profiles (Hein and Griebel, 2003). Collectively, pigs and humans share more than 80% of similarity in immune parameters. The majority of human genes, which were lost through evolution in the mouse, were retained in the pig, with chemokines and both IL-10 and chitinase family members being mostly conserved (Dawson et al., 2013; Dawson, 2011). Spleen perfusion models have already been described both for humans (Buffet et al., 2006) and pigs (Boxall, 1969), but the innovative aspect of this study is the perfusion and infection of organs sourced from the food chain, therefore strongly reducing the need of experimental animals in pre-clinical research. So far, ethical and economic concerns limited the use of pigs to study infectious diseases. With this new ex vivo model we propose to overcome these limitations by providing a new ethical and cost-effective tool that aims to investigate the dynamics of bacterial infections and to produce results that are more easily and effectively translated to humans.

2 Materials and methods

Spleen retrieval

Spleens were obtained from Large White pigs weighing 45-60 kg (Seven pig spleens have been harvested and perfused for this study), which were sourced from Joseph Morris abattoir (South Kilworth, Leicester, UK) following the routine slaughtering procedure. Animals received adequate husbandry, and necessary measures were taken to minimize pain, distress, and suffering during the slaughtering process in accordance with the UK and EU laws (EC, 2009). Pigs were killed by terminal exsanguinations according to Home Office regulations. At this stage, blood was harvested (1 L) from the jugular vein in non-sterile conditions and 25000 IU of heparin were added to prevent coagulation. Intact spleens were retrieved within 5 minutes post-mortem; following median laparotomy and sternotomy, the celiac trunk was accessed to isolate the main splenic artery and vein. Other vessels were clamped and tied, and the spleen was resected as en bloc. The en bloc spleen was then transferred to an ice tray where further detailed dissection was carried out. A 10-French catheter was inserted into the splenic artery via the celiac trunk origin and 1 liter of Soltran preservation solution (Baxters, UK) containing 5,000 IU of heparin (LEO Laboratories Limited, UK) and 10,000 IU of human urokinase (Syner-Medica Ltd, UK) was flushed to remove any residual blood clots. Organs were then transported to the lab in bags containing preservation solution on ice.

Ex-vivo spleen perfusion

Ex-vivo perfusion was achieved by means of an extracorporeal circuit similar to those used for cardiopulmonary extracorporeal bypass surgery (Medtronic Inc., Minneapolis, Minnesota - United States) (Fig.1b). The time between the slaughter procedure and the perfusion start was in the range of 75-90 minutes. Normothermia was ensured by the use of a heat chamber set at 39°C (that allowed arterial temperature to reach 37°C) while the oxygen supply was provided by an oxygenator at a rate of 2 L flow/min. Perfusion was performed at a constant pressure of 80 Hg/mm for the duration of the experiment. Perfusion was maintained for 6 hours and the oxygenated blood was recirculated from the reservoir via the perfusion circuit to the splenic artery (Fig.1b). Epoprostanol sodium (500 µg) was added to prevent vascular stricture due to ischemic-reperfusion injury (Gravante et al., 2012; Gravante et al., 2009), thus increasing vascular dilatation to provide sufficient oxygen supply.

Bacteria preparation and inoculation

The S. pneumoniae strain D39 (NCTC 7466) was grown in tryptic soy broth (TSB) medium and frozen stock aliquots containing 6,5×10⁷ Colony Forming Units (CFU) were prepared in TSB + 10% glycerol. For each infection experiment, whole stock of pneumococci was thawed on ice, and inoculated in the circuit 1 hour after the start of perfusion. Additional bacterial strains were assayed for survival in porcine blood to decipher the scope of this assay. These were Enterococcus faecalis (ATCC 29212), Escherichia coli (ATCC 25922), Listeria monocytogenes (ScotA), Pseudomonas aeruginosa (ATCC 10115), Salmonella enteritidis (SE147) and Staphylococcus aureus (ATCC 43300). These strains were grown in Brain Hearth Infusion (BHI) broth, and frozen aliquots were prepared in BHI + 10 % glycerol. For growth assays, 1x10⁶ CFU/ml of each bacterial strain were inoculated in 10 mL of heparinised pig’s blood and grown for 6 hours at 37°C. Samples were serially, ten-fold diluted and plated on BHI agar plates every hour to check the CFU numbers.

Blood and serum analysis

Arterial blood gas analysis was performed for each experiment immediately prior to bacterial inoculation and subsequently 2 hours and 4 hours post-infection. Several blood parameters were analyzed, including: pH, hemoglobin, glucose, lactate, Na⁺, Ca²⁺, K⁺, Cl⁻ to monitor the status of the organ and the possible development of acidosis or necrosis. Sera were collected every hour from both infected and uninfected control spleens. The sera were quantitatively tested for cytokines to measure the effect of the bacterial infection on immune regulation. In particular, Interleukin (IL-6) (R&D, P6000B) and Tumor Necrosis Factor-α (TNF-α) (R&D, PTA001) concentrations have been measured by Solid Phase Sandwich ELISA. IL-6 and TNF-α concentration have been calculated comparing their dose response curves to the standard curves.
Microscopy

Biopsies of the perfused spleens were collected at 0 minutes, 30 minutes, 2 hours, 4 hours and 5 hours after inoculation of bacteria or PBS (negative controls). Samples were rapidly frozen in Optimal Cutting Temperature (OCT) medium using dry ice and 2-methylbutane, before sectioning using a cryostat (Leica CM1850UV). 10 µm slices were sectioned and fixed with 4% paraformaldehyde on gelatin-coated slides. For confocal microscopy, samples were stained with several primary and secondary antibody combinations (see Tab. 1) to discern different cell types as previously described (Ercoli et al., 2018). Nuclear were stained with DAPI. Imaging was performed with an Olympus FV1000 confocal laser scanning microscope with 20X and 60X objectives. Scanning images of whole spleen sections were performed with a fully motorized Nikon Eclipse Ti microscope equipped with a Plan Fluor 10X/0.3 objective and an Andor iXonEM+ EMCCD DU 885 camera, with the NIS-Elements software. Finally for histological staining, samples were dried for 5 minutes and then stained with Hematoxylin and Eosin, as previously described (Fischer et al., 2008). All images were processed with Olympus Fluoview and ImageJ software (Schneider et al., 2012).

Neutrophil quantification

Cells were detected by microscopy on tissue sections, using a Ly-6G-specific primary antibody (Tab. 1). Perfused spleen sections at 0, 3 and 5 hours after infection were analyzed, an uninfected 5 hours perfused spleen was also used as a negative control. Mean Fluorescence Intensity (MFI) was calculated using the software ImageJ (Schneider et al., 2012). Numbers of neutrophils were enumerated in at least 15 fields from three independent biological replicates.

Statistical analysis

GraphPad Prism software version 6 was used to analyze all data. One-way Anova, with Tukey’s post-hoc test, was used to compare neutrophil distribution in the different samples. Results were considered significant when P values were <0.05. Error bars in all figures show the Standard Deviation, unless otherwise stated.

3 Results

3.1 Set-up of the normothermic porcine spleen perfusion model

A spleen perfusion was set-up for the first time on organs retrieved after slaughter. Therefore, in the final protocol several steps have been included to prevent coagulation, ischemic damage and necrosis. Porcine spleens were collected immediately after slaughter at the local abattoir. The organs were retrieved from animals bred exclusively for the food produce, thus the development of this model allowed replacement of protected animals. Following laparotomy, spleens were collected and the splenic artery cannulated while all the other arteries were ligated (Fig. 1a). Spleens were then flushed with 1 L of saline solution containing heparin (5000 IU) to remove the blood trapped in the organ. In parallel, blood from the same pig was collected and treated with heparin to avoid coagulation. Both organ and blood were then transported to the hospital where the extracorporeal perfusion circuit was pre-prepared. The set-up included a circuit that is composed by a centrifugal pump, a heat exchanger, an oxygenator and a reservoir for the blood (custom-made circuit, Medtronic) (Fig. 1b). All these components are connected to a perfusion machine (560 1.6 v Bio Console, Medtronic, 560 BCS1) that controls the blood pressure and measures constantly the flow rate (TX-50P Flow transducer, Medtronic, 95185-003). Before connection to the circuit, the organ was flushed with urokinase (10,000 IU) to dissolve eventual clots formed by the unwashed blood and then again with saline solution. The circuit was then filled with 1 L of heparinized blood (25,000 IU) and the flow was activated. At this stage, the spleen was connected to the circuit through the cannula that was still ligated to the main artery and the blood started to perfuse the spleen.

This ex-vivo perfusion technique was previously developed and refined in our lab using porcine livers and kidneys (Gravante et al., 2012). Throughout these studies, numerous technical modifications have improved the circuit (particularly the cardio-vascular component), and - as a consequence - also the organ viability throughout the experimental time course (Chung et al., 2015; Chung et al., 2012b; Chung et al., 2013). Nevertheless, the organ stress response to the harvesting and reperfusion processes (Gravante et al., 2009), in addition to the lack of homeostatic organs (kidneys, lungs) (Gravante et al., 2010) prevented the physiologic environment within the circuit to be stable for periods of longer than 6 hours. There are a few challenges with ex vivo organ perfusion, including thrombosis and various combinations of acid-base changes (Gravante et al., 2012) that can potentially affect the organ viability and function, limiting the duration of organ viability. To avoid these issues, an infusion saline bag containing Epoprostenol sodium (500 µg) and heparin (5,000 IU) was connected to the system with a flow of 20 ml/h. Furthermore, glucose (5%) was also infused at 5 ml/h to provide nutrients for the tissues. The established
settings adapted for the porcine spleen allowed us to run the perfusion for 6 hours without experiencing major changes in the organ physiological parameters, which is a sufficient time to study the early stages of bacterial sepsis.

**Fig. 1: Optimization of organ retrieval and set-up of the perfusion system.**
The spleen is collected immediately after slaughter from the abattoir. The splenic vein (1) and artery (2) are isolated and a cannula (3) is used to flush the organ with heparinized saline solution in order to remove excess of blood (a). The organ is then connected to a perfusion machine (b) and infused with autologous pig’s blood for 6 hours. The perfusion machine is composed by an organ chamber (1), a blood reservoir (2), a centrifugal pump (3), a water bath (4), an oxygenator (5), a pressure sensor (6), a connector for injections and sample collection (7) and the main control panel (8).

### 3.2 The perfused spleen as a model of infection to study bacterial sepsis

The porcine spleen perfusion model was tested as an alternative to the commonly used animal models to study the early stages of bacterial sepsis. To assess whether this model could be used to study different bacterial species, a panel of bacterial strains was tested for growth and survival in porcine blood. The results revealed that Gram-negative bacteria could survive but not proliferate in porcine blood, while all Gram-positive bacteria were capable of survival and replication (Fig. 2). This finding was in line with the superior complement resistance of Gram-positive bacteria and highlighted their better suitability for use in this model. The Gram-positive bacterium *Streptococcus pneumoniae* was selected for further infection experiments, not only because it is often associated with sepsis in humans, but especially because of the crucial role that the spleen is reported to have in fighting systemic infections caused by this bacterium (Deniset et al., 2017; Hosea, 1983; Brown et al., 1981; Ercoli et al., 2018). To minimize bacterial contamination, the autologous blood used for the perfusion was pre-treated with specific antibiotics (10 µg/ml Colistin and 5 µg/ml Nalidixic acid), which are not active against *S. pneumoniae* at these concentrations. One hour after the start of perfusion, organs were injected with 6.5x10⁷ CFU of *S. pneumoniae* (n=4) or with PBS as a negative control (n=3). Perfusions were run for 5 hours post-infection (6 hours in total). Serial blood and serum samples and spleen biopsies were collected at defined time-points to analyze whether the organ was able to maintain its clearance capacity under these conditions, and if the effects of bacterial infection on the *ex-vivo* spleen mirrored those observed *in vivo*, by using experimental animals.

**Fig. 2: Survival of different bacterial species in heparinized pig’s blood.**
A panel of *Enterococcus faecalis* strain ATCC 29212, *Escherichia coli* strain ATCC 25922, *Listeria monocytogenes* strain ScottA, *Pseudomonas aeruginosa* strain ATCC 10115, *Salmonella enteritidis* strain SE147 and *Staphylococcus aureus* strain ATCC 43300 was tested for growth and survival in porcine blood. 1x10⁶ CFU of each strain were incubated in whole heparinized pig’s blood for 5 hours and samples were plated for CFU counting every hour. Gram-positive bacteria were better capable of survival and growth in porcine blood, while Gram-negative bacteria survived, but did not grow.
3.3 Assessment of organ functionality

The correct functionality of splenic circulation was assessed by checking that the organ was bleeding only from the main splenic vein. Keeping the blood pressure constant at 80 mmHg, the flow rate rapidly increased and it became stable between 0.1-0.15 L/min for the duration of the perfusion (Fig. 3a). These parameters provide a measurement of the resistance of the organ and were monitored for the remainder of the perfusion (Fig. 3a). An excessive increase in the flow rate denotes that the organ no longer provides physiological resistance and may start to enlarge affecting the filtering functionality. Blood gas analysis was performed on blood samples collected at the beginning of the perfusion, after 2 hours and 4 hours. Glucose, lactate, pH, O₂, CO₂, hemoglobin and electrolytes concentration (all key facets of functional organ physiology) were measured throughout the perfusion and infection procedures. Tracking of these parameters over time was performed to exclude the occurrence of acidosis resulting from the formation of ischemic areas and necrosis. The blood gas values, pH (Fig. 3b) and electrolytes levels of the uninfected group (Fig. S1) remained stable throughout the duration of the perfusion, thus confirming the absence of necrotic processes and acidosis. In the infected group, lactate and hemoglobin increased and decreased respectively, thereby showing a worsening of the organ caused by infection (Fig. 3b). Of note, the pH levels remained within the physiological levels also in the infected spleen (Fig. 3b). After bacterial addition to the circuit, we assessed the organ clearance capacity by measuring its ability to gradually trap the bacteria. CFU counts in blood samples demonstrated that the ex-vivo organs were capable of complete blood bacterial clearance after 4 hours (Fig. 3c). Interestingly, in an inverse correlation, the number of bacteria in the spleen increased over time due to bacterial replication, in accordance with what we have recently reported for S. pneumoniae (Ercoli et al., 2018).

Fig. 3: Measurement of perfused spleen blood parameters.
One hour after the start of perfusion, the spleen was injected with 6.5x10⁷ CFU of S. pneumoniae (n=4) or with PBS (n=3). The perfusions were run for 5 hours after the injection and serial blood samples and spleen biopsies were collected at defined time-points. Blood pressure was kept constant at 80 mmHg and the flow rate was measured during the perfusions as a marker of the organ functionality, as an excessive increase in flow rate indicates poor filtration and loss of organ resistance. The flow rate observed both in the infected (red line) and in the uninfected (black line) samples was stable and within physiological parameters (A). Blood parameters were measured to exclude the occurrence of acidosis resulting from the formation of ischemic areas and necrosis. Values for pH, lactate and hemoglobin are reported for the infected (red line) and the uninfected (black line) blood samples. A t-test was used for statistical analysis (*P<0.05, **P<0.01 and ns=not significant) (B). CFU counts were performed on blood samples and serial biopsies in the infected spleens and showed that bacteria injected into the circuit were gradually trapped by the spleen and disappeared from the blood after 4 hours (C). After 2 hours, 20% of the original bacteria were shown to be trapped in the spleen and continued to increase over time, probably due to bacterial replication (D).

3.4 The architecture of porcine spleen after perfusion
Conservation of splenic architecture after perfusion has been assessed using microscopy analysis. Confocal imaging on multiple uninfected spleen sections confirmed the absence of defects in the organ structure after perfusion. As shown in Fig. 4a we could not observe significant differences in the organ structure between the beginning (left panel, t=0) and the end (right panel, t=6h) of the perfusion. To analyze spleen microarchitecture and characterize the immune cell distribution in the perfused organs, three adjacent 10 µm sections (to ensure identical microarchitecture) were prepared from uninfected pig spleens following 6 hours of perfusion and were stained for peri-follicular macrophages (CD169⁺), red pulp macrophages, T cells and neutrophils (Fig. 4b). The repertoires of primary and fluorescently labelled secondary antibodies used for fluorescent imaging are shown in Table 1. Staining of CD169⁺ macrophages allowed the identification of the peri-follicular areas, distributed in ring structures across the section (Fig. 4b; red staining). Areas of red pulp could be identified by fluorescent imaging of red pulp macrophage populations (Fig. 4b; yellow stain), making up the vast majority of the spleen section. Finally, T cells could

doi:10.14573/altex.1805131s
be identified in the peri-arteriolar sheets (PALS), whereas neutrophil populations were found in the red pulp (Fig. 4b; green and magenta staining respectively). Overall, microscopy analysis showed a good preservation of the immune cell distribution and we could not observe any abnormality in the follicle and PALS structure.

Since CD169+ macrophages have been recently indicated as crucial for pneumococcal splenic infection (Ercoli et al., 2018), we compared their distribution in mice and pigs (Fig. 4c). Spleen sections were stained to identify the localization of follicles (light blue) and CD169+ cells (red). As expected, we observed the CD169+ cells to only localize at the edge of the white pulp in mice. In pigs, the CD169+ macrophages were mainly localized in the peri-follicular area, with some of them found in the PALS, in close analogy to what is reported for humans (Mebius and Kraal, 2005). In Fig. 4d, a model of the CD169+ macrophages distribution in mice and pigs is reported. There are clear differences in the structure of the organ and in the distribution of the CD169+ cells between the two species, suggesting that at least for pneumococcal infection - which is caused by a human specific pathogen - the use of a model similar to humans can help in the translation of future findings.

Fig. 4: Splenic architecture is maintained during perfusion
Immunohistochemistry and fluorescent microscopy were performed to assess the organs architecture and immune cell composition after perfusion and bacterial uptake. Representative fluorescent microscopy images of uninfected spleen sections showed a preserved morphology and immune cell distribution (A) at the beginning (left panel) and at the end (right panel) of the organ perfusion. Subsequent sections of 6 hours perfused spleen have been stained with three antibody combinations to confirm the absence of defects in immune cells distribution (B). T cells are shown in green, neutrophils in magenta (left panel), CD169+ macrophages (indicating the peri-follicular area) in red (middle panel) and CD163+ macrophages (indicating the red pulp) in yellow (right panel). Each staining was performed using an antigen-specific anti-pig primary antibody and a fluorescent conjugated secondary antibody. A direct comparison of splenic architecture of mouse (left panel, archive picture not published in Ercoli et al., 2018 article) and pig (right panel) is shown in panel C, especially focusing on the CD169+ macrophages distribution – a key difference in the splenic architecture of these species. CD169+ cells are shown in red in both samples, while the light blue staining indicates the white pulp in the mouse spleen, and the follicles and endothelium in the pig one. Antibody details are provided in Table 1. A schematic representation of the comparison of the splenic micro-architecture of the two species is then shown in panel D, where it is particularly evident the difference in follicle organization and in the CD169+ cell distribution.

3.5 Early stages of bacterial sepsis in the spleen perfusion model
Spleen sections were analyzed after infection to verify the presence of any tissue damage caused by the infection. To determine the level of preservation of the organ during perfusion, a number of different immunohistochemistry and histological staining were performed on 10 µm sections from both uninfected and infected spleen biopsies. Hematoxylin and eosin staining was used to investigate the viability of the tissue across the infection time course, and as a validation of this model for histology studies. We observed a good preservation of the splenic tissue after perfusion in the control uninfected sample (Supplementary Data. Fig. S2) and also in the infected spleen both at the beginning (0 hours) and at the end (5 hours) of the infection (Fig. 5a). The red pulp and white pulp showed clear demarcation in control spleen and at early stages of infection. At 5 hours, the red/white pulp demarcation was slightly less clear due to expansion of the marginal zone at the periphery of the white pulp. This expansion is due to an increased number of cells with histological features in keeping with macrophages.

Confocal microscopy also confirmed that the microarchitecture of the organ was preserved 5 hours after infection (Fig. 5b). A time-course analysis was performed on spleen biopsies collected from each experiment, looking at bacterial numbers and distribution. As seen in Fig. 3c the bacterial number increased in the spleen even when the blood was fully cleared. This suggested bacterial replication taking place within the perfused spleen, and confocal microscopy confirmed the formation of clusters of bacteria within splenic cells at later time-points (Fig. 5b). The number of bacteria in each cluster increased over time and they reached the maximum size at the last time-point as showed in Fig. 5c. As we observed formation of foci of infection in the spleen, we tested if non-resident immune cell subtypes could have been recruited to the infection site. Neutrophils, in particular, were observed to increase in numbers during the infection and to co-localize with the bacteria in the red pulp (Fig. 5d-e). The average number of neutrophils surrounding a bacterial cluster also increased with time (Fig.
5e), showing that, to fight the infection, the organ is still capable of signaling for alternative innate clearance mechanisms to the phagocytosis mediated by resident macrophages. Interestingly, in the uninfected control perfusion, the neutrophils number was comparable to that of the early time points (Fig. 5e).

Macrophage release of IL-6 and TNF-α in the blood as a response to bacterial infection was also tested and the results are reported in Fig. 5e. Although the slaughtering process and the non-sterile collection of the blood may initiate cytokine release before bacterial challenge, as it has been reported for TNF-α concentration (Liu et al., 2010), we could notice a significant increase in the serum concentration of this cytokine in the infected sample. Despite having a lower starting concentration, IL-6 increased at the same rate in both uninfected and infected samples, and the levels reached were comparable to what observed in previous ex vivo organ perfusion studies (Gravante et al., 2009; Chung et al., 2012a).

---

**Fig. 5:** Clusters of replicating pneumococci have been found in the perfused spleen.

Hematoxylin and eosin staining of infected spleen sections showed good preservation of the splenic tissue at all time points (A). The white pulp (left panel) and red pulp (right panel) show a clear demarcation at early stages of perfusion (top panels). At 5 hours, the red pulp/white pulp demarcation is slightly less clear due to expansion of the marginal zone at the periphery of the white pulp (bottom panels). Confocal microscopy analysis of spleen sections showed the appearance of clusters of pneumococci (indicated by green circles) within the tissue after perfusion and infection, but no overall difference in the splenic architecture (B). Single pneumococci (green) are trapped immediately after the infection by the perfused spleen (C, left panel). At later time-points an increase in number of bacterial cells in each cluster was observed (C, right panel). Staining was performed using an anti-type 2-capsule (green) and an anti-pig CD169 primary antibodies (red), 647-conjugated phalloidin (magenta) and DAPI (blue). Neutrophil localization and recruitment in the perfused spleens were analysed by microscopy (D). Uninfected (D, left panel), 2 hours (D, middle panel) and 5 hours infected (D, right panel) spleen sections were stained. In the red pulp (magenta), neutrophils (red), which are in proximity of bacterial clusters (green), increase in number during time.

A measurement of the mean fluorescence intensity (MFI) of neutrophils in these tissue sections at different time points showed an increase only at the late stage of splenic infection (E). Numbers of neutrophils in proximity to bacterial clusters were also counted, and showed an increase overall time, likely due to chemotactic recruitment. 15 fields from 3 independent samples were analysed for each time point. Error bars indicate standard deviation. One-way ANOVA with Tukey’s post-hoc test was used for statistical analysis (*P<0.05, **P<0.01, ***P<0.001, ****P<0.0001 and ns=not significant). Antibody details are provided in Table 1.

IL-6 and TNF-α levels were measured by ELISA assay in the sera collected from the infected (red lines) and uninfected (black lines) blood during the perfusion experiment (F). Lines indicate the medians, error bars the standard deviation.
4 Discussion

A porcine spleen perfusion model of infection was established using organs retrieved from routine slaughter for food production. The development of this technique involved the refinement of three different processes: organ collection, perfusion and bacterial infection. Special care was taken during organ collection, especially in removal of all blood trapped in the spleen after pig slaughtering. Failure in this process could result in the blockage of blood circulation during perfusion and formation of ischemic areas, which would hamper experimental studies. Extensive washes with anticoagulant solution and thrombolytic agents have been applied to prevent blood vessel damage. Moreover, a final confirmation of the absence of obstacles to blood circulation was provided by the measurement of blood flow and pressure during the perfusion process. The perfusion process was monitored constantly to assess organ viability and functionality. Blood gas analysis and immunohistochemistry have been performed to exclude major changes in the functionality and microarchitecture of the organ as a result of the perfusion process. Whilst less than optimal blood–gas parameters were obtained at the start of the infection – likely a result of the damage incurred during slaughter – physiologically relevant conditions were still achieved throughout the experiment. Regarding bacterial infection, the major bacterial human-specific pathogen S. pneumoniae was tested with respect to dose and time of infection. Studies of the effect of pneumococcal infection in the perfused spleens were investigated, focusing on splenic clearance, cytokine release (starting cytokines levels are also affected by the slaughtering process), neutrophil recruitment and bacterial survival. We showed that a number of features of our model mimic those of data shown in mice and humans, particularly: rapid clearance of pneumococci from the blood, release of tumor necrosis factor following infection, neutrophil recruitment across the infection site, and more recently, intracellular replication of pneumococci within splenic macrophages (Ercoli et al., 2018).

Since 2005 our group has used an ex-vivo perfused porcine organ model to study organ physiology and investigate the implications using these models with respect to human physiology (Chung et al., 2013; Gravante et al., 2012; Gravante et al., 2010; Gravante et al., 2009). Most of the biochemical, immunologic and pathological changes observed in this model are very similar to those observed in animal research, bridging the gap between in vitro and in vivo studies (Daniel et al., 2018). This confirms that our model is a reliable and inexpensive method for the study of organ physiology and, as shown with this study, also its response to systemic infection (Gravante et al., 2012; Gravante et al., 2010; Gravante et al., 2009). Importantly, an ex-vivo spleen circuit is also disconnected from physiological extrinsic regulatory control systems (neurological, hormonal or chemical), which are present in complex organisms, and allows for a detailed focused evaluation of the organ intrinsic response to infectious stimuli without systemic factors that are present in experimental in vivo models and in clinical studies. The use of perfused porcine spleens to study bacterial sepsis is not only advantageous because of the replacement of experimental animals, but also provides a model that is very similar to humans and that could both help in the translation of rodent studies and to predict the efficacy of antimicrobial therapies. In our study, we have focused on the optimization of this model as a tool to study host-pathogen interactions. The possibility to perform multiple sampling, time-course studies and live imaging on the same perfused organ opens the road to investigate the fine dynamics of the strategies that both bacteria and host employ during infection.

This innovative system is flexible (different organs and pathogens can be tested), reduces the number of required experiments (as multiple and/or serial sampling can be performed on the same organ), and improves the translatable nature of the data generated (since porcine organs are much more similar to those of humans than are those of rodents). For these reasons, our model will address the unmet need for an ex vivo model in the fields of infection and anti-infective drug discovery and will be particularly important for the study of the initial phases of invasive diseases. A future application of the model could be testing the efficacy of antimicrobial compounds with particular emphasis on intracellular pathogens eradication. New refinements of the organ collection will be tested in order to prolong the perfusion time up to 12 hours. Reduction of the ischemic damage will be the key point, mainly solvable by reducing the collection time (surgery) and by improving the flushing technique (using thrombolytic agents). In this way, the bactericidal activity of new molecules could be assessed in a system resembling the early stages of bacteremia. Organ perfusion infection models have been developed in the past, both with rodents and human organs. Mouse liver and rat intestine have been tested respectively with Candida albicans and Salmonella enteritidis to investigate host-pathogen interactions (Schwocho and Moon, 1981; Boyle et al., 2016), while the human spleen was infected with the parasite Plasmodium falciparum to test organ clearance and processing functionality in pathophysiological conditions (Buffet et al., 2006). The rodent organ perfusions did not overcome the limitations of studying infection diseases in a poorly relevant model, and the latter was limited by human sample availability. Importantly, the key advantage of our work is the replacement of animals used for research with abattoir sourced organs.

Due to multiple samplings in our model, the data collected from one single infected pig organ (in our experimental series) correspond to data obtained using 48 mice. Since January 2015 more than 1200 articles have been published using mice to study organ-specific infections caused by Streptococcus pneumoniae, Staphylococcus aureus, Listeria monocytogenes, Uropathogenic (UPEC) Escherichia coli and Salmonella enterica. An estimate based on the average reported number of mice used in 5% of these papers brings the total number of mice to 71600. Obviously, this estimate is conservative as only accounts for animals reported in publications, thus the real number of experimental animals in use is strongly underestimated. Moreover, this calculation only refers to mice and does not take into consideration other animal species that might be equally substituted with the use of the ex vivo perfusion models of infection. Piglet infection models are the most direct comparison to our model. Since January 2015, about 90 articles have been published reporting the use of more than 2900 piglets to study bacterial infections.

In conclusion, we report the development of an ex vivo porcine spleen perfusion model sourced from pigs slaughtered for food production, optimized for the study of bacterial infection. We show that organ function is maintained for 6 hours – sufficient time to investigate the early events preceding sepsis. This model mimics many hallmarks of bacterial disease, including rapid clearance of bacteria from the blood, and increases in pro-inflammatory cytokine production following...
infection. We also demonstrate the utility of this model for histological studies. Most importantly, this model provides an avenue for translation of data obtained in rodents to immunologically distinct humans and reduces the need for use of experimental animals.
