The genetics of hypertrophic cardiomyopathy

Mohammed Akhtar*, Perry Elliott

ABSTRACT

Hypertrophic cardiomyopathy (HCM) is most commonly transmitted as an autosomal dominant trait, caused by mutations in genes encoding cardiac sarcomere proteins\(^1\)\(^-\)\(^3\). Other inheritable causes of the disease include mutations in genes coding for proteins important in calcium handling or that form part of the cytoskeleton\(^4\)\(^-\)\(^6\). At present, the primary clinical role of genetic testing in HCM is to facilitate familial screening to allow the identification of individuals at risk of developing the disease\(^7\)\(^,\)\(^8\). It is also used to diagnose genocopies, such as lysosomal\(^9\)\(^-\)\(^11\) and glycogen storage disease which have different treatment strategies, rates of disease progression and prognosis\(^12\)\(^-\)\(^14\). The role of genetic testing in predicting prognosis is limited at present, but emerging data suggest that knowledge of the genetic basis of disease will assume an important role in disease stratification\(^15\)\(^-\)\(^17\) and offer potential targets for disease-modifying therapy in the near future\(^18\).
GENETIC ARCHITECTURE OF HCM

Familial HCM is characterized by locus and allelic heterogeneity, with a high frequency of novel individual mutations. The first genetic mutation to be identified was a single base substitution in the MYH7 gene encoding ß-myosin heavy chain, a key component of the cardiac sarcomere. Since then, many different mutations in MYH7 and other genes of the cardiac sarcomere have been identified. In 5–10% of cases, HCM is caused by mutations in genes that cause metabolic disorders, neuromuscular disease, or inherited genetic syndromes including Noonan syndrome (Figure 1).

THE CARDIAC SARCOMERE

Every cardiomyocyte is composed of myofibrils that run longitudinally along the cell and are transversely subdivided into contractile units called sarcomeres. The sarcomere constitutes the fundamental motor unit of the cardiomyocyte and is composed of two principal components—the thick filament composed of around 300 molecules of myosin, each made up of 2 protein units of ß- or α-myosin heavy chain and 4 myosin light chain molecules, and the thin filament composed of repeating actin molecules, closely associated with the regulatory troponin complex (troponin T (TnT), troponin I (TnI)).

Figure 1. Representation of the percentage of hypertrophic cardiomyopathy cases accounted for by pathogenic mutations in sarcomeric and non-sarcomere genes. Elliott PM, et al; 2014 ESC Guidelines on diagnosis and management of hypertrophic cardiomyopathy: The Task Force for the Diagnosis and Management of Hypertrophic Cardiomyopathy of the European Society of Cardiology (ESC), European Heart Journal 2014; 35 (39): 2733–2779, doi:10.1093/eurheartj/ehu284. and troponin C (TnC) and α-tropomyosin. An additional protein, cardiac myosin-binding protein C, contributes to the regulation of actin–myosin interaction and cross-bridge kinetics (Figure 2).

Muscle contraction results from the interaction between myosin and actin in which the globular head of the myosin molecule bends towards and then binds to actin, contracts, releases actin, and then initiates a new cycle. The links between the myosin head and actin are called cross-bridges; the contraction of the myosin S1 region which requires the hydrolysis of ATP to release energy is called the power stroke.

Electrical activation of the heart and cardiomyocyte contraction are coupled through the intracellular movement of calcium. Depolarisation of the cardiomyocyte cell membrane activates the L-type voltage-dependent calcium channels in the T tubule causing an influx of calcium into the cell that triggers opening of ryanodine-receptor channels in the adjacent sarcoplasmic reticulum with a rapid increase in cytosolic calcium. Calcium binds to TnC, inducing an allosteric conformational change in TnI and TnT that is transmitted to tropomyosin and exposes the myosin-binding sites of actin allowing the cross-bridges to form. The myosin heavy chain head, with ADP and inorganic phosphate bound to its nucleotide-binding pocket, then interacts with the exposed actin-binding sites followed by the release of ADP and inorganic phosphate, which occurs simultaneously with the power stroke. ATP then binds to the nucleotide-binding pocket of the myosin heavy chain head, which detaches from actin and myosin then hydrolyses ATP into ADP and inorganic phosphate restarting the contraction cycle.
SARCOMERE MUTATIONS IN HCM

Mutations in βMYH7 and MYBPC3 account for 60–70% of HCM patients with pathogenic variants. Mutations in other sarcomere and associated protein genes are listed in Table 1. Mutations in MYH7 are predominantly missense, with single nucleotide-base substitutions resulting in a non-synonymous single amino acid substitution. In contrast, the majority of mutations in MYBPC3 are nonsense mutations due to insertion/deletions, splice-site variants or frameshifts causing a premature stop codon that results in a truncated protein transcript.

The majority of missense mutations are believed to have a dominant negative effect in which the mutant protein is incorporated into the sarcomere, but its interaction with the normal wild-type protein disrupts normal sarcomeric assembly and function (poison polypeptide hypothesis). Individual missense mutations may change an amino acid in a highly-conserved residue, alter important kinase domains (affecting ligand interaction) or change surface-exposed portion of a molecule altering protein-protein interaction. Missense mutations can also cause protein misfolding and accelerated degradation by ubiquitin-proteasomal surveillance pathways.

In truncating mutations, haploinsufficiency is thought to be the major disease mechanism. The reported absence of detectable truncated myosin-binding protein C in western-blot analysis of myectomy specimens of patients with this mutation may be due to nonsense mediated mRNA decay of abnormal transcripts or ubiquitin-mediated proteasomal degradation of aberrant truncated protein.

Allelic heterogeneity can be partly explained by the effect of different mutations on the structure and function of the complete peptide. β-myosin heavy chain, for example, consists of a globular head, an α-helical rod and a hinge region. The globular head contains binding sites for ATPase and actin as well as interaction sites for regulatory and essential light chains in the head-rod region. The majority of disease-causing β-myosin heavy chain mutations are found in one of four locations: the actin binding site, the nucleotide binding pocket, the hinge region adjacent to the binding site for two reactive thiols and in the α-helix close to the essential light chain interaction site. Thus, different effects on protein function might be expected depending on the position of the mutation.

It has been speculated that the HCM disease phenotype results from reduced contractile function caused by altered actin-myosin interactions, and consequent inappropriate compensatory hypertrophic remodelling. However, some MYH7 mutations are associated with increased cardiomyocyte mechanical contractile forces in vitro and show an increase in calcium sensitivity, leading to increases in tension generation and ATPase activity. Animal and cell studies have also confirmed altered calcium homeostasis as a key contributor to the pathophysiological processes that lead to the development of LV hypertrophy.

Troponin T mutations account for less than 5% of all cases of HCM but often show a particular phenotype. TNNT2 mouse models show varying degrees of myocyte disarray and fibrosis with minimal LVH, in common with TNNT2 disease expression in humans. Troponin-mutated mice exhibit severely impaired myocardial relaxation, independent of the degree of fibrosis, and consistent with the finding of increased calcium sensitivity. Some studies suggest that some TNNT2 mutations are associated with a high incidence of sudden death which may also relate to calcium loading in cardiomyocytes.

Findings from murine models of HCM suggest that the increased contractility seen with some mutations is at the expense of inefficient ATP utilization. Furthermore, animal

and human studies suggest that HCM is associated with depleted energy stores and 
abnormal ATP/ADP ratios\(^{56-59}\). Inefficient utilization of ATP is also seen in metabolic 
disorders or mitochondrial cytopathies, which can produce a pattern of LV hypertrophy 
similar to that in sarcomeric HCM.

Recently, mutations in genes encoding z-disc proteins including myozenin (MYOZ2), 
telethonin (TCAP), alpha-actinin-2 (ACTN2), muscle LIM protein (CRP3) and nexilin (NEXN) 
have been implicated in HCM\(^{31}\). Some mutations in Z-disc proteins have a pleotropic 
effect, causing an HCM phenotype in certain individuals and a DCM phenotype in others 
within the same family\(^{60}\).

**CHILDHOOD-ONSET HCM**

The importance of sarcomeric protein gene mutations in childhood hypertrophic 
cardiomyopathy is unknown. The observation that the development of left ventricular 
hypertrophy in individuals with familial disease often occurs during the period of somatic 
growth in adolescence has led to the suggestion that sarcomeric protein disease in very 
young children is rare\(^{61,62}\). However, studies of children with HCM have shown that, as 
in adults, sarcomeric protein gene mutations account for approximately 50% of cases of 
idiopathic HCM, even in infants and young children\(^{63,64}\).

**PHENOTYPIC VARIABILITY**

There is a substantial variation in the expression of identical mutations indicating that 
other genetic and possibly environmental factors influence disease expression. The 
effect of age is perhaps the best characterized factor, most patients developing ECG 
and echocardiographic manifestations of the disease after puberty and before the age 
of thirty\(^{65,66}\). Sex also appears to influence disease expression in sarcomere protein 
disease\(^{67,68}\). Other potential modifying factors include renin-angiotensin-aldosterone 
system gene polymorphism\(^{69-71}\), and the occurrence of homozygosity and compound 
heterozygosity\(^{72-74}\).

**GENETIC ADVANCEMENTS**

The impact of more rapid, cost-effective gene sequencing methods, together with 
improved cellular models including induced pluripotent stem cells, gene-editing 
technology, larger sequenced control cohorts and deep clinical phenotyping in cases 
means that we are at an exciting crossroads in the genetics of HCM. This provides 
researchers with significant opportunity to identify novel candidate causative genes and 
to potentially allow clearer genotype-phenotype correlations to be made, thereby laying 
the foundation for more personalised patient care.
