Abstract

Background: There is consistent evidence of a cumulative relationship between childhood adversity and psychosis, with number of adversities experienced increasing the probability of psychosis onset. It is possible that genetic factors moderate the association between childhood adversity and psychosis, potentially by influencing how an individual reacts biologically and/or psychologically following exposure to adversity, in such a way as to set them off on the path to psychosis. However, identifying the specific genetic variants involved and how they interact with childhood adversity remains challenging. We examined whether the association between cumulative exposure to childhood adversity and development of psychotic disorder was moderated by the COMT Val<sup>158</sup>Met, AKT1 rs2494732 or DRD2 rs1076560 polymorphisms, known to affect dopamine levels.

Methods: Participants were 285 first-presentation psychosis cases and 256 geographically-matched controls drawn from the Genetics and Psychosis (GAP) study. Childhood adversity was assessed using the Childhood Experience of Care and Abuse Questionnaire (CECA.Q) and blood- and cheek-derived genotype data were collected.

Results: Our findings revealed no main effect of COMT Val<sup>158</sup>Met, AKT1 rs2494732 and DRD2 rs1076560 polymorphisms on psychosis case status or reports of childhood adversity. Individuals reporting a history of multiple adversities were more likely to be psychosis patients than controls, regardless of their genetic risk. There was no evidence of candidate genotype by childhood adversity interactions in relation to psychosis onset.

Conclusion: These findings did not provide evidence of a possible role of COMT Val<sup>158</sup>Met, AKT1 rs2494732 or DRD2 rs1076560 genotypes in modifying the association between childhood adversity and onset of psychosis.

Keywords: AKT1, childhood trauma, COMT, DRD2, gene–environment, GxE, schizophrenia
1. Introduction

Exposure to adverse events in childhood is associated with around a 2 to 4-fold increased risk of psychosis (Morgan & Gayer-Anderson, 2016). Furthermore, childhood traumatic experiences tend to co-occur such that being exposed to one type of adversity increases the risk of exposure to another, with a cumulative effect of trauma on psychosis (Shevlin et al., 2008).

However, very little is known about how exposure to childhood adversity is translated into biological risk for psychosis. One possibility is a gene-environment interaction, whereby a pre-existing genetic vulnerability modifies the biological response to adverse childhood experiences leading to the development of psychotic symptoms. We have previously explored whether genetic susceptibility to psychosis (via family history of psychosis and a polygenic risk score for schizophrenia) interacts with reported exposure to childhood adversity to predict onset of psychotic disorders but did not find any evidence for this (Trotta et al., 2015, 2016). Here we consider whether functionally-relevant polymorphisms might interact with adverse childhood experiences to lead to the development of psychosis. Specifically, dysregulation of the dopamine system has been found among individuals exposed to childhood adversity (De Bellis et al., 1999; Gerra et al., 2007; Heim et al., 2000; Pruessner et al., 2004) and is also postulated to be important in the pathogenesis of psychosis (Howes et al., 2009, 2017; Kapur, 2003; Moore et al., 1999; Spitzer, 1995; Walker & Diforio, 1997; Walker et al., 2008). Therefore, genes involved in the regulation of dopamine levels in the brain would be plausible biological candidates for interaction with childhood adversity. Indeed several such genes, including Catechol-O-methyltransferase (COMT), AKT1 and the dopamine receptor type 2 (DRD2), have been linked with psychosis (Bolog et al., 2012; Cheng et al., 2006; Egan et al. 2001; Kapur et al., 1999; Karege et al., 2012; Li et al., 1996; Norton et al., 2007; Thiselton et al., 2008).
The *COMT* gene plays an important role in the metabolism of dopamine in the central nervous system (Garris et al., 1993). A single nucleotide polymorphism (SNP) in the *COMT* gene, located on chromosome 22q11.2 (Winqvist et al., 1991), causes an amino acid change from valine to methionine at position 158 (Val<sup>158</sup>Met), with a 3- to 4-fold variation in enzymatic activity between Val/Val genotype and Met/Met genotype (Chen et al., 2004a; Weinshillbom et al., 1999). Specifically, Met/Met genotype carriers have the lowest *COMT* activity, whereas the Val/Val carriers have the most enzyme activity (Mannisto & Kaakkola, 1999). Diverse gene-environment interactions have been reported for *COMT* Val<sup>158</sup>Met in moderating risk for psychotic disorder (Bilder et al., 2004; Tunbridge et al. 2006), for example, in the case of cannabis use in adolescence (Caspi et al., 2005; Henquet et al., 2009) and daily life stress (Peerbooms et al., 2012). Specifically, the Val allele has been associated with self-reported psychotic experiences in the context of stress and cannabis use in a Dutch adult population sample (Vinkers et al., 2013) and with the stress of army induction in a Greek male conscript sample (Stefanis et al., 2007). *COMT* Val<sup>158</sup>Met has also been associated with increased schizotypal personality trait scores in Val/Val individuals exposed to higher levels of childhood trauma (Savitz et al., 2010). Therefore, it seems a relevant candidate gene for testing in interaction with childhood adversity to predict the presence of psychotic disorders.

Another candidate to test for a gene x childhood adversity interaction is the *AKT1* gene, located on chromosome 14q32, which has been reported to be associated with schizophrenia (Freyberg et al., 2010; Mathur et al., 2010). *AKT1* codes for a protein kinase (Protein kinase B, PKB), that forms an integral part of a cascade mediating dopamine signalling in the striatum. Animal and human studies have found that psychosocial stress, including childhood adversity, leads to a sensitization of mesostriatal dopamine neurotransmission, which might increase the risk of developing psychotic symptoms (Egerton
et al., 2016; Howes et al., 2004). Moreover, a GxE interaction has been reported between an AKT1 gene polymorphism, rs2494732, and an environmental risk factor, cannabis use, in the pathogenesis of psychosis: carriers of the C/C genotype were most likely to develop psychotic illness after smoking cannabis (Di Forti et al., 2012; van Winkel et al., 2011a, 2011b). To date, no studies have investigated an AKT1 gene x childhood adversity interaction in psychosis onset, though a pilot study focusing on the potential relationship of stress and psychosis showed that higher subclinical psychotic experiences were associated with chronic and severe stress and AKT1 rs2494732 in a sample of students (Bruenig et al., 2014).

A third potentially relevant SNP is rs1076560 in the DRD2 gene (chromosome 11q23), located within intron 6, which has been found to be associated with schizophrenia (Ripke et al., 2014). This SNP specifically regulates the expression of the dopamine receptor long (D2L) and short (D2S) isoforms, responsible for dopamine synthesis and release in the frontal cortex (Zhang et al., 2007). In line with previous research on AKT1, the role of the DRD2 gene has only been investigated in the context of the association between cannabis use and psychosis, with subjects carrying the T risk allele showing an increased risk of having a psychotic disorder in the context of cannabis use compared to GG carriers (Colizzi et al., 2015a; 2015b).

We used a first-presentation psychosis case-control sample to investigate whether the association between cumulative exposure to childhood adversity and development of psychotic disorder was moderated by the COMT Val158Met, AKT1 rs2494732 and DRD2 rs1076560 polymorphisms, as these have been shown to be involved in the regulation of dopamine and linked to psychosis. Of the selected candidate genes, only DRD2 elicits genome-wide support for a role in the pathogenesis of schizophrenia (Ripke et al., 2014), although this does not preclude the potential involvement of all three genes in the moderation of childhood adversity, an exposure whose genetic basis has not yet been interrogated on a
genomic scale. Therefore, we investigated each candidate gene separately in interaction with childhood adversity to explore whether there were specific moderating effects of the selected polymorphisms on the presence of psychotic disorder.

2. Methods

2.1. Sample

The sample was drawn from first-presentation psychosis cases from the Lambeth, Southwark, Lewisham, and Croydon adult in-patient and out-patient units of the South London & Maudsley (SLAM) Mental Health National Health Service (NHS) Foundation Trust and unaffected community controls who participated in the Genetics and Psychosis (GAP) study (Di Forti et al., 2015). Participants from this study were included if they had been assessed regarding childhood adversity and provided an analysable sample of DNA. Inclusion criteria for cases were: aged 18–65 years, presenting to psychiatric services for the first time with a psychotic disorder (codes F20–29 and F30–33 from the International Classification of Diseases [ICD-10]; World Health Organization, 1992), and resident within tightly defined catchment areas in Southeast London, UK. Exclusion criteria were: organic psychosis; intelligence quotient (IQ) under 70; previous contact with services for psychosis, and transient psychotic symptoms resulting from acute intoxication.

Controls were aged 18–65 years and recruited from the local population living in the area served by the Trust. Efforts were made to obtain a control sample that was representative of the general population in age, gender, ethnicity, educational qualifications, and employment status. The Psychosis Screening Questionnaire (PSQ; Bebbington and Nayani, 1995) was administered to all potential control group participants; individuals were excluded if they met criteria for a psychotic disorder.
2.2. Measures

2.2.1. Childhood adversity

The Childhood Experience of Care and Abuse Questionnaire (CECA.Q; Bifulco et al., 2005) was employed to retrospectively elicit information on a range of adverse childhood experiences from participants. Physical abuse by the main mother and father figures (usually, but not necessarily, the biological parents), sexual abuse by any adult or an individual at least 5 years older than the recipient, separation from a parent for at least 6 months, death of a parent, taken into institutional care, and disrupted family arrangements, all prior to 17 years of age, were assessed. The CECA.Q was read out to all participants during face-to-face interviews to improve the accuracy of the fixed category responses obtained. This questionnaire has been shown to have good internal consistency (Smith et al., 2002), satisfactory levels of test-retest reliability over 7 years in a similar psychosis sample (Fisher et al., 2011), and reasonable concurrent validity with other measures (Bifulco et al., 2005; Fisher et al., 2011; Smith et al., 2002).

2.3. Genotyping procedures

Seventy-five percent of DNA samples used originated from blood and 25% from cheek swabs. A comparison of genotype results for 360 individuals with overlapping blood and cheek swab DNA revealed there was 100% concordance between blood- and cheek-derived genotype data (Di Forti et al., 2015). The DNA was extracted using a standard phenol-chloroform extraction procedure. A Taqman SNP assay was used to genotype the COMT gene at the rs4680 locus, the AKT1 gene at the rs2494732 locus, and DRD2 at the rs1076560 locus (kit format at http://www.appliedbiosystems.com). After an initial Taq polymerase activation/DNA denaturation step, samples were subjected to PCR reaction following standard Applied Biosystem dry DNA protocol. Amplification products were
analyzed using the Applied Biosystems 7900HT Fast Real-time PCR System. Genotype calls were made based on a clustering algorithm with quality value of 95%.

2.3.1. Validation of self-reported ethnicity

To confirm self-report of ethnicity, genetic ancestry was derived using a panel of 57 ancestry informative genetic markers. These were genotyped using iPLEX technology developed for the MassArray platform (Sequenom Inc., San Diego, California) and an ancestry score was derived using the program Structure (Falush et al., 2003) to implement a model-based (Markov Chain Monte Carlo) clustering algorithm. Individuals who scored between 96% and 100% for genetic cluster membership were used to create a three-way ancestral axis based on Black African, European Caucasian, and Asian ancestry. These reference groups were used to index genetic ancestry for the remaining sample. Eighty-nine percent of participants had information on both self-reported ethnicity and ancestry markers. The level of overall agreement between self-reported and genetic ethnicities (96%) was reassuringly high.

2.4. Ethics

This study was part of the GAP study, which was granted ethical approval by the South London and Maudsley and Institute of Psychiatry Local Research Ethics Committee (REF: 05/Q0706/158). All cases and controls included in the study gave informed written consent to the publication of data originating from the study.

2.5. Data analysis

Data were analyzed using Stata 11 (Stata, College Station, Texas). A composite variable was computed to summarize how many of the different adversities had been
experienced by each individual, following the guidelines published by Bifulco et al. (2005).
This ‘total adversity’ score involved summing the dichotomous CECA.Q severity subscale scores (range 0-6) and then recoding the total into an ordinal scale of 0 (none), 1 (single adverse experience), and 2 (multiple adverse experiences).

For COMT Val<sup>158</sup>Met polymorphism, the number of Val alleles and genotypes were coded as 0 (no Val alleles, Met/Met genotype), 1 (one Val allele, Val/Met genotype), and 2 (two Val alleles, Val/Val genotype). The AKT1 gene (rs2494732) was coded as 0 (no risk alleles, TT genotype), 1 (one risk allele, C/T genotype), and 2 (two risk alleles, C/C genotype). The DRD2 gene (rs1076560) was coded as 0 (no risk alleles, G/G genotype), 1 (one risk allele, G/T genotype), and 2 (two risk alleles, T/T genotype).

Cuzick’s (1985) non-parametric test of trend for ranks across ordered groups was performed using the ‘nptrend’ command in STATA to assess associations with psychosis and childhood adversity across the COMT, AKT1 and DRD2 genotypes. This test is considered more sensitive to trends across three or more categories than the standard chi-square test and is also robust to deviations from Hardy Weinberg Equilibrium (HWE) (Cuzick, 1985). The results of this trend test were used to assess the presence of gene-environment correlations between COMT, AKT1, DRD2 genotypes and total childhood adversities in psychosis cases and controls. The main associations and interactions between childhood adversity and COMT, AKT1 and DRD2 genotypes on the presence/absence of psychosis were tested using a generalized linear model with the binomial distribution and identity link function specified (Wacholder, 1986) to estimate risk differences (RD) and 95% confidence intervals (CI). We tested for interaction with an additive model as it has been argued to be more in line with biological interaction (Knol et al., 2007). All analyses were adjusted for proportion of black genetic ancestry. GxE interaction analyses were conducted firstly with additive genetic models and then using dominant and recessive genetic models for full transparency. COMT
Val^{158}Met genetic models were coded as follows: additive (0=Met/Met, 1=Val/Met, 2=Val/Val), dominant (0=Met/Met, 1=Val/Met or Val/Val), and recessive (0=Met/Met or Val/Met, 1=Val/Val). AKT1 rs2494732 genetic models were coded as follows: additive: (0=TT, 1=C/T, 2=C/C), dominant (0=TT, 1=C/T or C/C), and recessive (0=TT or C/T, 1=C/C). DRD2 rs1076560 genetic models were coded as follows: additive: (0=G/G, 1=G/T, 2=T/T), dominant (0= G/G, 1=G/T or T/T), and recessive (0= G/G or G/T, 1= T/T).

3. Results

3.1. Sample characteristics

Information on number of childhood adversities was available for 285 first-presentation psychosis patients and 256 unaffected controls. Those who completed the CECA.Q did not differ significantly from non-completers in terms of gender (cases: $\chi^2=3.757$, $p=0.055$; controls: $\chi^2=0.658$, $p=0.445$), but controls who completed the questionnaire were more often of non-White ethnicity (controls: $\chi^2=8.119$, $p=0.017$ cases: $\chi^2=1.368$, $p=0.500$) and significantly younger than the rest of the GAP sample (controls: mean age 29 vs. 32.8 years, $t=3.183$, $p=0.002$; cases: $t=1.705$, $p=0.089$). However, in practice this was only an average of 4 years difference in age which should not have had a significant impact on memory of past events (Fisher et al., 2011).

The demographic characteristics of the sample and the main association between number of childhood adversities in cases and controls are provided in Supplementary Table 1. Psychosis cases had a lower level of education ($\chi^2=32.60$, $p<0.001$), and were more often of non-White ethnicity ($\chi^2=76.73$, $p<0.001$) compared with controls, and thus we controlled for these variables in the subsequent analyses. There was no significant difference between psychosis cases and controls in terms of gender ($\chi^2=2.57$, $p=0.065$) and age ($t=0.342$, $p=0.733$). Total number of childhood adversities experienced was associated with having a
psychotic disorder ($z=4.97$, $p<0.001$), with first-presentation psychosis patients more than twice as likely as controls to report exposure to one (Adjusted OR=2.01, 95% CI 1.30-3.11, $p=0.002$) or multiple (Adjusted OR=2.17, 95% CI 1.31-3.61, $p=0.003$) childhood adversities.

Table 1 shows the distribution of the $COMT$ Val$^{158}$Met, $AKT1$ rs2494732, and $DRD2$ rs1076560 genotypes in cases and controls along with the findings of the Hardy-Weinberg Equilibrium (HWE) tests. The $COMT$ genotypes were in HWE amongst controls ($\chi^2=2.881$, $p=0.089$), however in the cases the HWE was breached ($p=0.034$). The distribution of the $COMT$ genotypes was similar between psychosis cases and controls and this was confirmed by a non-significant result for Cuzick’s non-parametric trend test ($z=0.46$, $p=0.645$). The $AKT1$ rs2494732 polymorphism allele was in HWE amongst both cases ($\chi^2=0.525$, $p=0.468$) and controls ($\chi^2=0.030$, $p=0.864$). There was no main association between the $AKT1$ rs2494732 polymorphism and psychosis in this sample ($z=0.32$, $p=0.748$). Similarly, the $DRD2$ genotypes were in HWE amongst cases ($\chi^2=0.009$, $p=0.923$) and controls ($\chi^2=0.017$, $p=0.895$), and there was a non-significant result for Cuzick’s non-parametric trend test ($z=-0.95$, $p=0.341$) indicative of no association between $DRD2$ rs1076560 and psychosis status in this sample.

3.2 Gene-environment correlation

The proportion of participants with each genotype was compared for those with and without a history of childhood adversity (Table 2). There was no significant difference in the number of childhood adversities reported by $COMT$ genotype amongst cases ($z=1.05$, $p=0.292$) or controls ($z=1.07$, $p=0.283$). Similarly, no significant gene-environment correlations were found overall between the $AKT1$ genotype and childhood adversity amongst cases ($z=-0.96$, $p=0.338$) or controls ($z=1.50$, $p=0.134$), as well as between $DRD2$ genotype and childhood adversity in cases ($z=-1.35$, $p=0.176$) or controls ($z=0.67$, $p=0.503$).
3.3. Genotype by childhood adversity interaction in psychosis

Table 3 presents the main effects of the total number of childhood adversities and their interactions with COMT, AKT1 and DRD2 additive genetic models on the presence of psychosis. The total number of adversities was associated with psychosis regardless of COMT, AKT1 and DRD2 genotypes (all $p$'s<0.05). No significant interactions with childhood adversity were found under an additive genetic model in all the polymorphisms (all $p$'s>0.05). Additionally, no significant interactions were found for multiple adversities with COMT, AKT1 and DRD2 under dominant or recessive genetic models (Supplementary Table 2).

4. Discussion

No main associations between the selected polymorphisms and psychosis case status or childhood adversity were found in this sample. This is in line with previous findings on COMT Val$^{158}$Met which have been inconsistent (Glatt et al., 2003) and even a large family-based study found only modest associations between this variant and schizophrenia (Chen et al., 2004b). Moreover, recent meta-analyses concluded that there was no, or at best only weak, evidence of COMT genotype increasing risk for psychosis (Fan et al., 2005; Munafo et al., 2005; Ripke et al., 2013). Our findings on AKT1 rs2494732 polymorphism and psychotic disorder in this sample are in contrast with some previous studies that found an association between this candidate gene and schizophrenia (Bolog et al., 2012; Karege et al., 2012; Norton et al., 2007; Thiselton et al., 2008). Furthermore, despite the DRD2 gene being identified in a recent genome-wide association study (Ripke et al., 2013) as a risk gene for
schizophrenia, our results did not support this finding in a more broadly defined psychotic disorder sample.

There was, as expected, a main association between total number of adverse childhood experiences and presence of psychotic disorder but this occurred regardless of genotype for the polymorphisms studied. This is in line with our previous paper that showed an association between childhood adversity and psychosis onset, regardless of schizophrenia polygenic risk score (Trotta et al., 2016). However, it is in contrast to previous studies that have shown the greatest impact of stressful events on psychotic symptoms amongst individuals with at least one COMT Val allele compared to those homozygous for the Met allele (Simons et al., 2009; Stefanis et al., 2007), although other studies have found greater sensitivity for the Met/Met genotype (Myin-Germeys et al., 2006; van Winkel et al., 2008a). This discrepancy could be partly due to differences in the demographics of the samples, type of psychotic outcome or intensity of the stressors studied (Simons et al., 2009; van Winkel et al., 2008b) more than the specific alleles.

Disruptions in postnatal rearing conditions can lead to profound and lasting changes in the responsiveness of mesocorticolimbic dopamine neurons to stress in animals (Brake et al., 2004; Hall et al., 1999; Pani et al., 2000) as well as in humans (Collip et al., 2008; Pruessner et al., 2004). According to the social defeat hypothesis, long-term exposure to the experience of social defeat or social exclusion may lead to sensitization of the mesolimbic dopamine system (and/or increased baseline activity of this system) and thereby increase the risk for schizophrenia (Cao et al., 2010; Selten et al., 2013; van Nierop et al., 2014b). Therefore, exposure to childhood adversity might lead to dysfunctional emotional responses (e.g. greater anticipation of threatening events) (Freeman et al., 2013; Bentall et al., 2014) which in turn are associated with an anomalous dopaminergic response (Deutch et al., 1990),
facilitating the onset of psychotic symptoms (Goto et al., 2007; Kapur, 2003; Kapur et al., 2005).

There was no evidence of genotype by childhood adversity interactions for presence of psychotic disorder. These results are in line with a previous study which found no interaction between COMT Val^{158}Met genotype and childhood maltreatment in predicting schizophréniform disorder at 26 years of age (Caspi et al., 2005). However, previous animal studies have shown an interaction between COMT and maternal care in mice (Zhang et al., 2005). A three-way interaction between the COMT genotype Val alleles, childhood maltreatment, and adolescent cannabis use has also been reported in the etiology of psychotic experiences (Alemany et al., 2013; Vinkers et al., 2013). Similarly, previous studies found an interaction between AKT1 rs2494732 and DRD2 rs1076560 with cannabis use in first-episode psychosis (Di Forti et al., 2012; van Winkel et al., 2011b; Colizzi et al. 2015a; 2015b). Therefore, it might be that the lack of an interaction effect between COMT, AKT1, DRD2 and childhood adversity on psychosis in the current sample could be due to other environmental factors influencing psychosis case status.

4.1 Limitations

It is important to consider the current findings in light of several limitations. The most important consideration in this regard is low a priori probability of interaction and/or low statistical power (Duncan & Keller, 2011), issues that are more common in candidate gene approaches (Burton et al., 2009). Our results should thus be interpreted with caution. Although these findings need to be replicated in a larger-scale study, we have previously shown in the same sample that DRD2 and AKT1 polymorphisms interact in increasing the risk of psychosis in cannabis users compared to non-users (Colizzi et al., 2015b). Therefore, our negative findings could suggest that other environmental factors might be interacting
with the dopamine genetic pathway, such as substance use (Di Forti et al., 2012) or stressful life events occurring in adulthood (Beards et al., 2013), to lead to the development of psychosis. Furthermore, this study may have failed to detect an interaction also because of the utilization of retrospective self-report measures (i.e. CECA-Q; Bifulco et al., 2005).

Moreover, this sample was multiethnic. This may be important in light of the differences in allele frequency across the main ethnic groups (African and European origin; Knowler et al., 1988). However, to account for the possibility of population stratification, all analyses were controlled for the potential confounding effect of genetic ancestry to reduce this potential bias in the results. In this sample, one SNP was also in Hardy–Weinberg disequilibrium. As SNPs in Hardy–Weinberg disequilibrium are less powerful, and do not tend to increase false-positive results (Fardo et al., 2009), the reported results are unlikely to be caused by Hardy–Weinberg disequilibrium, especially given the absence of quality control issues (the genotypes were successfully identified at call rates of between 79% and 85%).

We also chose to focus on functionally-relevant candidate genes as we previously found no interaction with childhood adversity and a schizophrenia PRS in relation to psychosis (Trotta et al., 2016). However, this approach also has limitations. One potential way to overcome the limitations from both single candidate gene and PRS studies would be to identify co-expression pathways of risk genes in schizophrenia (Harrison & Weinberger, 2005). Because genes interact with each other and are co-regulated by a common biological process (e.g., mRNA), the investigation of gene pathways has been argued to have greater biological validity than single gene and PRS approaches (Mitra et al., 2010). For instance, Weighted Gene Co-expression Network Analysis (WGCNA) integrates information related to multiple genes and identifies clusters of co-expressed genes based on similar genetic profiles across individuals (Monaco et al., 2018). Recent findings have, for example, identified a cluster for the \textit{DRD2} pathway prefrontal co-expression, which has been found to be
associated with greater prefrontal activity and working memory impairment in schizophrenia (Pergola et al., 2017). Therefore, the identification of specific molecular pathways could improve the understanding of the genetic factors related with psychotic disorders and should be explored in interaction with childhood adversity and other environmental factors in future studies.

In conclusion, the current study did not provide evidence of an interaction between specific candidate genes and childhood adversity in psychosis onset and, therefore, in this particular sample, the specific genotypes involved in the dopamine pathway did not seem to moderate the effect of adverse childhood experiences on presence of psychotic disorder.
