Keywords: frontotemporal dementia, tau, PET, biomarkers
Introduction

Mutations in the microtubule associated protein tau (MAPT) gene are a common cause of inherited frontotemporal dementia (FTD), and result in the deposition of pathological tau protein in the brain. Tau positron emission tomography (PET) may enhance in vivo diagnosis and testing of tau-based therapies in FTD, however, few tau ligands have been validated in FTD. The $[^{18}\text{F}]$AV-1451 ligand was developed to assess in vivo tau accumulation and has consistently been shown to bind to tau in individuals with Alzheimer’s disease (AD), but less work has focused on the non-AD tauopathies, including FTD. Autoradiography studies of $[^{18}\text{F}]$AV-1451 have shown strong binding in regions of neurofibrillary tangles matching the pattern of paired helical filament (PHF) immunochemistry, but have not shown strong binding to non-PHF-tau.

In $[^{18}\text{F}]$AV-1451 studies conducted in FTD spectrum disorders, not only does the ligand not bind strongly to non-PHF tau, but there is significant in vivo binding reported in conditions where no tau is expected at all e.g. in patients with semantic variant primary progressive aphasia and with C9orf72 expansions where TDP-43 pathology is usually found. $[^{18}\text{F}]$AV-1451 also displays both off-target binding in the basal ganglia, and an age-related increase in binding in cognitively healthy controls. Nevertheless, this ligand has shown strong binding in a subset of FTD-causing MAPT mutations, including V337M and R406W that are associated with PHF-tau pathology. $[^{18}\text{F}]$AV-1451 may therefore be useful in detecting tau pathology in some genetic forms of FTD that result in similar structural conformations of tau to that of AD. Here we describe longitudinal $[^{18}\text{F}]$AV-1451 PET imaging from a patient with FTD due to a Q351R mutation located on exon 12 of the MAPT gene.

Methods

Participants

A patient with a Q351R MAPT mutation in her mid-60’s as well as six healthy controls (three male and three female: mean age at scan 44.7 years, range 29.1 to 68.3 years) underwent $[^{18}\text{F}]$AV-1451 PET and
T1-weighted MR imaging. The Q351R *MAPT* mutation carrier was also scanned 1 year later. The study was approved by the local ethics committee and all participants gave their consent to take part.

**Scanning procedures**

All participants were scanned on a Siemens Biograph 6 PET-CT scanner with Truepoint gantry. Dynamic PET data were acquired continuously following intravenous bolus injection of $[^{18}\text{F}]$AV-1451 for 120 mins in 3D-mode. A low-dose CT scan of the head was also acquired.

Dynamic images were reconstructed using a filtered back projection algorithm (direct inversion Fourier transform), with isotropic voxel size of $2\text{mm}^3$. Corrections for decay and random counts were performed, and attenuation and scatter were corrected based on the CT scan acquired preceding PET acquisition. Rigid head motion correction using image registration was performed to align the reconstructed dynamic PET frames. Frames affected by mismatched attenuation correction were identified by visual inspection and excluded from kinetic analysis. All participants also underwent T1-weighted volumetric MR imaging on a 3T Siemens Trio scanner.

A simplified reference tissue model (SRTM) with basic functions was used to generate non-displaceable binding potential ($BP_{ND}$) values. $BP_{ND}$ values were calculated using the pons as a reference region. Regions of interest were defined on the co-registered T1-weighted MR image using a previously described parcellation methodology generating six cortical and five subcortical regions including a combined medial temporal (amygdala and hippocampus) region.
Analyses

*T*-scores were calculated and differences in BPND between the carrier (at both baseline and follow-up) and controls were compared using standard single case methodology, with a significance level set at 0.05.

Results

Clinical history

A detailed case report of the patient until the age of 62 has been previously reported6. In her mid-60’s when she had the baseline PET scan, she carried a diagnosis of behavioural variant FTD. Her disease had been very slowly progressive, initially starting in her mid-40s with an amnestic presentation and quite subtle behavioural change. A change in personality only became prominent in her late 50s. By the mid-60s she was apathetic, but disinhibited at times, with a sweet tooth, and impaired executive function as well as both episodic and semantic memory difficulties. At the time of the baseline scan her MMSE was 24/30 and FTLD-CDR sum of boxes was 18, whilst at the follow-up scan her MMSE had decreased to 18 and her FTLD-CDR had increased to 19.5. Her father developed a similar illness in his 40s, dying at the age of 55. Genetic screening had revealed a novel Q351R mutation (NM_001123066.3: c.2057A>G), not previously reported in other families.

PET imaging analysis (Figure 1a and b)

At baseline, the patient’s BPND was higher than the mean control BPND in all regions, and higher than the maximum control BPND in the frontal, temporal and insula cortical and all subcortical regions. A significant difference from controls was seen in the insula region cortically, and the medial temporal, putamen, and pallidum regions subcortically.

At follow-up, the patient’s BPND values had increased across all cortical and subcortical regions after one year. These were now higher than the maximum control BPND in all cortical and subcortical regions,
with a significant difference from the control group in the same regions as at baseline but also now the
temporal region cortically and caudate and thalamus regions subcortically.

The patient’s regional BPND values negatively correlated with brain volumes both at baseline ($r^2 = -0.745$, $p=0.008$) and follow-up ($r^2 = -0.791$, $p=0.004$) (Supplementary Table 1, Supplementary Figure 1).

**Discussion**

In this study we show increased binding of the [$^{18}$F]AV-1451 ligand in an individual with a Q351R
*MAPT* mutation in both cortical and subcortical regions, with higher binding potential in all regions at
longitudinal follow-up later. The findings are consistent with the known pattern of symmetrical antero-
medial temporal and insula lobe and basal ganglia involvement seen in *MAPT* carriers.

As with prior studies, we found some binding of the [$^{18}$F]AV-1451 ligand in healthy controls, particular centres around the basal ganglia, although this was lower than in the patient, even at the
baseline scan. The nature of such off-target binding remains unclear, although it is not likely to
represent binding to tau.

There has been little investigation of longitudinal change in [$^{18}$F]AV-1451 binding. Here we provide
evidence that a very variable change is seen over a one-year interval in a patient with a slowly
progressive form of FTD. In cortical regions, the percentage increase varied from 13-130%, whilst in the
subcortical regions it varied from 1-89%, with the lowest increase seen in the pallidum where the most
off-target binding was seen in controls.

No one with a Q351R mutation has yet to come to *post mortem*. However, the mutation sits between two
mutations known to have PHF-tau pathology (V337M and R406W). Strong binding of [$^{18}$F]AV-1451
has been shown in both mutations \textit{in vivo}, suggesting that the strong binding observed in this patient is also indicative of PHF-tau pathology, although further studies will be needed.

This study suggests that the $[^{18}F]$AV-1451 ligand may be a useful biomarker in at least a subset of $MAPT$ mutations that result in PHF-tau pathology in FTD. However, further work needs to be done in characterising tau ligands that may be useful across the spread of non-AD tauopathies.
