Background

- The obesity epidemic in children and young people is a leading public health priority in the UK, with 20% of 11-15 year olds in England being obese.1
- Insufficient physical activity (PA) and excessive sedentary behaviour (SB) are linked with increased fatness and risk for chronic diseases such as diabetes.3
- Adolescence is a critical stage for the development of body composition profiles and chronic disease risk, and also a period when individuals become increasingly inactive.4
- In the UK, little is known on the objectively measured PA and SB levels of obese adolescents (already at higher risk for chronic diseases due to their increased adiposity), or their relationship with fatness and cardio-metabolic indicators.

The aims of this study were to:
1) describe the PA and SB levels of obese adolescents;
2) investigate the association of SB and moderate-to-vigorous PA (MVPA) with adolescent’s fatness and cardio-metabolic indicators.

Methods

HELP is a randomized controlled trial of a complex lifestyle intervention for obese adolescents (BMI>95th centile of UK 1990 reference, age: 12-19 years) recruited from the community (London, UK), involving motivational interviewing and other psychological elements. Baseline measures were used in this study.

- Total, low- (LDL) and high-density lipoprotein cholesterol (HDL), triglycerides, insulin and glucose were obtained from fasting blood samples. Height, weight, waist circumference, and fat mass (4-limb bio-impedance) were measured by trained staff. Body mass index (BMI) was calculated (kg/m²) and z-scores derived using the UK 1990 reference5, and fat mass index (FMI) was derived.6
- ActiGraph accelerometers (15-s epochs) assessed PA/SB. Time in SB, light and MVPA was derived with Evenson et al’s7 cut-points, and participants were included for analyses if providing ≥3 valid days (≥10 hours wear-time).
- Normality of data was checked with the Shapiro-Wilk test, and sex differences were assessed with Chi-square or t-tests/Mann-Whitney U tests.
- Univariable (adjusted for wear-time) and multivariable linear regression models were used to investigate the association of MVPA and SB with fatness and cardio-metabolic indicators. Wear-time was excluded from multivariable analyses due to colinearity issues (VIF >6.0; correlations with MVPA/SB >0.6).

Results

- Of the 174 adolescents assessed at baseline, 102 provided complete data for accelerometry, fatness and metabolic indicators, and were included for analysis.
- Included participants were not significantly different from those excluded, except for insulin (median: 11.1 vs. 15.7 mmol/L respectively) and glucose levels (mean: 4.4 vs. 4.6 mmol/L respectively; both p<0.01).
- Participants had a mean age of 15.2 years (±2.1), with the majority being girls (65%) and of white British (37%) or black Caribbean (35%) ethnicity. Table 1 describes the fatness and metabolic profiles of the included sample.

Table 1 – Participants’ fatness and metabolic characteristics.

- Participants spent most of their day in SB (median: 73.2%; IQR: 69.1%, 76.3%), and only a small amount of time in MVPA (median: 4.1%; IQR: 3.0%, 5.4%).
- Boys did more daily MVPA than girls (p=0.004), and were more likely to meet national PA guidelines (24.3% vs. 9.2%; p=0.04).

Conclusions

- Most adolescents did not meet current PA guidelines, and spent most of their day in SB.
- Although causality cannot be inferred, results highlight the importance of promoting MVPA to improve the body composition profiles of obese adolescents.
