Abstract
In an increasing number of states and countries, cannabis now stands poised to join alcohol and tobacco as a legal drug. Quantifying the relative adverse and beneficial effects of cannabis and its constituent cannabinoids should therefore be prioritised. Whereas newspaper headlines have focused on links between cannabis and psychosis, less attention has been paid to the much more common problem of cannabis addiction. Certain cognitive changes have also been attributed to cannabis use, although their causality and longevity are fiercely debated. Identifying why some individuals are more vulnerable than others to the adverse effects of cannabis is now of paramount importance to public health. Here we review the current state of knowledge about such vulnerability factors, the variations in types of cannabis, and their relationship to cognition and addiction.

1. Introduction
For millennia, cannabis has been used medically and for religious purposes, most notably in China and India. The plant and its many constituent cannabinoids are now becoming increasingly important in modern medicine, particularly in the treatment of chronic pain and spasticity\textsuperscript{1}. A much more widespread global use is for pleasure\textsuperscript{2}: the ‘stoned’ experience varies widely across individuals but often includes euphoria, a heightened awareness of music and colour, and the tendencies to eat a lot and to giggle profusely\textsuperscript{2}. Despite its pleasurable effects, most scientific research has focused on adverse consequences of using the drug, such as addiction, cognitive impairment and possible increased risk of psychotic illness\textsuperscript{3, 4}.

We do not know how patterns of use will change as legalisation proliferates, but even a small percentage increase in the current 182 million users worldwide\textsuperscript{5} will mean a considerable surge in absolute numbers. Are we now able to use existing evidence about the less desirable effects of cannabis use to help us to look forward to the future?

This article aims to survey our current state of knowledge about the effects of cannabis and then pinpoint how we should be increasing our understanding of the effects of cannabis, given its potentially soaring future use. We first summarise the variety of unique ingredients in cannabis and outline how its use affects cognition, learning and memory. We survey evidence of how the effects of the drug vary according to the maturational state of the brain and then go on to discuss cannabis addiction and the mental health problems that are often related to it. Finally, we identify the important gaps in our current knowledge and look to the future in terms of both research and the current tide of changes to the legislation of cannabis.

2. **Cannabis: a plant with many forms**

Purple Haze, Northern Lights, charas, skunk, resin, grass, marijuana, weed… The multitude of names for cannabis in part reflects variations in genetics, growing conditions, processing, and
constituent cannabinoids and terpenoids in different strains of the plant. Of the roughly 100 unique ingredients in cannabis that are called cannabinoids, most research to date has focused on the two most prominent of these: delta-9-tetrahydrocannabinol (Δ⁹-THC) and cannabidiol (CBD). These two compounds appear to have a range of opposing effects on the human brain and behaviour. For example, Δ⁹-THC acutely impairs learning, produces psychosis-like effects and increases anxiety⁶, whereas CBD can enhance learning⁷ and has antipsychotic⁸ and anti-anxiety⁹ properties in humans. When taken together, CBD may ameliorate the harmful effects of Δ⁹-THC¹⁰,¹¹.

Δ⁹-THC acts as a partial agonist at cannabinoid CB₁ receptors (CB₁Rs), whereas CBD has a complex range of pharmacological actions. For example, although CBD has low affinity for CB₁R it can attenuate CB₁ agonist effects in brain even at low concentrations (e.g. providing functional antagonism of CB₁R signaling)¹². Conversely, CBD reduces the cellular reuptake and hydrolysis of the endogenous cannabinoid anandamide (AEA) in brain¹²,¹³ Neuroimaging studies have documented opposing effects of Δ⁹-THC and CBD on blood oxygenation level-dependent (BOLD) signal during performance of several cognitive and emotional tasks, including striatal response during memory retrieval and amygdala response to fearful faces¹⁴.

Over the past two decades, the Δ⁹-THC content of street cannabis has risen dramatically, whereas its CBD content has decreased to negligible levels. For example, in the United States, the Δ⁹-THC content of street cannabis rose from 4% in 1995 to 12% in 2014¹⁵. In Europe¹⁶,¹⁷ and Australia¹⁸, high-potency cannabis containing ~15% Δ⁹-THC and less than 0.1% CBD now dominates the market. Thus, the type of cannabis available years ago differs considerably from that sold today, limiting the relevance of older longitudinal cohort studies (for example, the New Zealand Birth Cohort study, see Box 1) to the mental health and cognitive function of contemporary users. In the United States, the cannabis that the National Institute of Drug Abuse
supplies to researchers for experiments generally has less than 4% Δ⁹-THC, and so findings from these experiments have limited implications for modern-day cannabis users.

3. Cognition, learning and memory

Endocannabinoids (eCBs) are, in a sense, the brain’s own natural cannabis system, and Δ⁹-THC and other CB1R agonists alter brain levels of eCBs¹⁹.²⁰. eCBs are neuroactive lipids that participate in a range of physiological processes including reward, motivation, emotional homeostasis, pain processing, and synaptic plasticity contributing to learning and memory. At present, the best-characterized eCBs are N-arachidonylethanolamide (anandamide; AEA) and 2-arachidonoylglycerol (2-AG)²¹,²² and both of these lipids exert agonist activity at CB1Rs and CB2Rs. Owing to their lipid nature, AEA and 2-AG are not stored in vesicles but are synthesized on an ‘on-demand’ basis, and as such brain eCB levels are critically reliant on the balance between evoked biosynthesis and subsequent clearance by intracellular enzyme-mediated hydrolysis. eCBs are crucial in certain forms of neuronal plasticity, and Δ⁹-THC has been shown to disrupt long-term potentiation (a model for learning and memory) and long-term depression in preclinical studies²³. In this section, we consider the acute and longer-term effects of cannabis on cognition, learning and memory, as well as effects potentially persisting after an individual has stopped using the drug. We also review evidence on the impact of starting cannabis use early in adolescence.

**Acute effects.** Acute effects are transient and seen in the time period during which the individual is intoxicated with the drug (e.g. feeling ‘stoned’ for around 5-120 minutes when smoked). A single dose of cannabis or its main active ingredient Δ⁹-THC robustly and dose-dependently impairs working and episodic memory²⁴,²⁵. Memory impairments occur however the drug is administered, but the onset of effect is more rapid when it is inhaled or given
intravenously than when it is ingested orally. Specifically, the encoding of new memories is impaired during cannabis intoxication and this leads to subsequent deficits in recalling these memories; by contrast, the retrieval of old memories that were consolidated when not under the influence is unaffected. Cannabis-induced working-memory deficits are seen more in the ability to manipulate information while it is ‘online’ (for example, when doing mental arithmetic) than in the ability to simply retain it for brief periods (for example, when remembering a telephone number before dialling it). Whereas on placebo, brain activity in the dorsolateral prefrontal cortex (DLPFC) increases linearly with a task’s working memory load, acute dosing with Δ⁹-THC prevents this load-associated increase in DLPFC activity²⁶.

These effects on memory are consistent with the extensive preclinical evidence of: the amnestic effects of cannabis in animal models; the high density of cannabinoid receptors in memory-associated brain regions such as the hippocampus, amygdala and prefrontal cortex (Figure 1); and observations that Δ⁹-THC induces disruption of plasticity (including long-term potentiation (LTP) and long-term depression (LTD)) in the hippocampus and decreases acetylcholine release here and in the prefrontal cortex (PFC) (Figure 2A).

Some studies report acute Δ⁹-THC-induced impairment of behavioural inhibition and increases in impulsivity, but findings on attention, decision-making and risk-taking tasks are mixed and task-dependent²⁵,²⁷. There is also some evidence that acute effects may vary depending on an individual’s previous level of use of the drug. Tolerance to the memory-impairing²⁸ and psychomotor effects²⁹ of acute Δ⁹-THC have been shown in individuals who use the cannabis more than once a week, probably reflecting a downregulation of cortical CB1Rs³⁰,³¹ (Figure 2B).

There is some evidence that acute effects of Δ⁹-THC cannabis on memory depend on the particular type of cannabis ingested. Smoking cannabis with higher levels of CBD protected
regular users against the acute memory-impairing effects of \( \Delta^9\text{-THC} \). Findings in cannabis-using volunteers replicated these protective effects of CBD on \( \Delta^9\text{-THC} \)-induced acute memory impairment. Indeed, CBD alone has been shown to enhance fear extinction learning in humans. This further supports the notion that CBD and \( \Delta^9\text{-THC} \) may have opposing effects on some of the neural substrates of human memory. A recent cross-sectional study found that CBD appeared to protect against the effects of \( \Delta^9\text{-THC} \) on hippocampal volume loss. Future research should determine whether chronic exposure to CBD might be protective in the longer term.

**Long-term effects.** Although in several countries legislation enables new studies of medical cannabis to use prospective, randomized controlled trial designs, to date studies of the neurocognitive effects of repeatedly using cannabis (that is, the long-term or chronic effects) have relied mainly on retrospective, self-reported drug use by people who choose to use cannabis recreationally, and, in most cases, illicitly. More objective indices of drug use can be obtained through hair samples, although such analysis has limitations (for example, they are influenced by hair dyes) and have been rarely used in studies. Long-term impairments in memory have been reported mainly in frequent, heavy users, but confounding factors make it difficult to establish cause–effect relationships between cannabis use and changes in neurocognitive function. Such factors include baseline cognitive function prior to drug use; use of other cognitively impairing drugs like alcohol; types of cannabis used; age at which use started; and mental health problems, including depression and cannabis addiction.

Case-control studies of non-acute effects of cannabis have produced inconsistent findings to date, but tend to mirror acute findings. The most consistently reported long-term effects in these studies are impairments of encoding new episodic memories, with some studies finding
persistent deficits in the first few days of abstinence but little evidence of persisting deficits at 28 days after use\textsuperscript{25}. Meanwhile, the findings for measures of working memory, attention and impulsivity are mixed. One study\textsuperscript{35} found no difference in decision making or risk taking between cannabis users and non-users who were matched for potential mental health confounds. However, poorer decision-making accuracy in users was significantly associated with the number of symptoms of cannabis addiction.

Functional neuroimaging studies often reveal subtle differences between chronic cannabis users and controls in brain activity during performance of cognitive tasks; again, the persistence and clinical importance of these differences remain to be determined. A systematic review\textsuperscript{36} of 43 studies concluded that chronic cannabis use may alter brain structure and function in both adult and adolescent users (particularly in the medial temporal and frontal cortices, and cerebellum). However, the findings of the mainly cross-sectional studies displayed remarkable heterogeneity and it was not possible to infer causation. Further, deficits are most consistently observed only among heavy users — those most likely to be addicted to cannabis. Cognitive changes related to chronic exposure to cannabis or Δ\textsuperscript{9}-THC observed in humans and in animal model studies (such as reduced inhibitory control and impaired decision making)\textsuperscript{27, 37, 38} are implicated in the maintenance of addiction\textsuperscript{39} in part by impairing the reversal of behaviors related to drug acquisition/taking that propel continued drug use despite negative consequences. It could thus be proposed that these cognitive changes may interact with genetic vulnerability factors to increase the risk of developing cannabis addiction.

Age-dependent effects: adolescence and adulthood. The eCB) system has a major role in neurodevelopmental and maturational processes including synaptic pruning and white-matter development, and these processes are especially prevalent during adolescence. As exogenous cannabinoids affect the functioning of the eCB system, it is plausible that prolonged use during adolescence disrupts the neurodevelopmental maturational processes during this
period\textsuperscript{40}. Thus, the human brain may be more vulnerable to drugs at the time when use of cannabis often begins.

Preclinical studies have shown that repeated exposure to $\Delta^9$-THC has a greater negative impact on the working memory, object recognition, and pre-pulse inhibition of adolescent than on adult rodents\textsuperscript{40}. Chronic administration of CB1R agonists or $\Delta^9$-THC to adolescent rats produces persisting impairments in object recognition memory that are not seen with the same treatment in adult rats\textsuperscript{41, 42}, as well as greater alterations in the level of expression of various hippocampal proteins (which may account for adolescent-specific memory effects\textsuperscript{42}). A single dose of $\Delta^9$-THC has also been found to result in greater acute impairments to spatial and non-spatial learning in adolescent rats than in adult rats\textsuperscript{43}.

The age-related effects of cannabis use on cognitive function may therefore be dependent on the maturational state of the neural circuits that are affected by the drug. This may reflect the fact that $\Delta^9$-THC induces perturbations in the crucial influence of the eCB signalling that is involved in brain development, for processes including neural proliferation, morphogenesis, neural migration and synaptogenesis\textsuperscript{44–46}. Consistent with this interpretation were the results of a study in which $\Delta^9$-THC was repeatedly administered over 6 months to adolescent monkeys in doses that corresponded well to human self-administration (approximately 1–2 joints, 5 days per week). This repeated administration blunted the usual pattern of accuracy improvements on a test of spatial working memory (which matures after object working memory), but not on an object working memory task\textsuperscript{47}. Thus, the persistent effects of $\Delta^9$-THC on cognition in animals are more evident when exposure coincides with the developmental stage during which cannabinoid-affected neural circuits are actively maturing.
Similarly, there is also accumulating evidence in humans that neurocognitive function and aspects of brain architecture are more disrupted by cannabis when individuals start using it during adolescence, although there is a scarcity of direct comparisons with adult users. Some structural imaging studies in adolescent and young adult cannabis users have reported decreased volume in several cortical and sub-cortical regions but findings across different studies vary considerably. For example, although structural differences between adolescent cannabis users and controls in orbitofrontal cortex (OFC) volume have been found, smaller volumes at 12 years of age were shown to predict cannabis use at 16, suggesting that differences in the OFC may be a vulnerability factor for use rather than a consequence. And although smaller hippocampal volumes in cannabis users have been associated with age of onset of use, this association appears less consistent does the association between reductions in the size of the hippocampus and the amount of use, suggesting that the structure of the hippocampus may be more affected by duration and intensity of exposure rather than by early use specifically.

Diffusion tensor imaging (DTI) studies have found poorer white-matter integrity (indexed by both lower fractional anisotropy and higher mean diffusivity) in adolescents who use cannabis frequently compared with control non-users. Further, reductions in those indices of white-matter integrity correlate with deficits in measures of neurocognitive performance.

Several functional MRI (fMRI) studies suggest that there is increased BOLD signal in task-related areas in young cannabis users compared with non-using controls. For example, Jager and colleagues assessed 13–19-year-old boys who had used cannabis at least 200 times in their lives and compared them with non-using, age-matched controls. The cannabis users showed greater activation in prefrontal regions during a working memory task than did controls. Overall, most functional imaging findings suggest that adolescent cannabis users
show increased recruitment of neural resources — potentially reflecting compensatory activity — in brain areas subserving task-related processing.

In terms of neurocognitive function, individuals who started using cannabis during adolescence have been reported to have greater deficits in visuospatial attention\textsuperscript{52}, verbal fluency\textsuperscript{53} and inhibition\textsuperscript{53} than do those who start in adulthood. Importantly, based on the Dunedin prospective cohort data, one study\textsuperscript{54} concluded that having cannabis addiction that started during adolescence and persisted into adulthood was associated with a decline of around 8 IQ points (Box 1). However, two recent, large-scale studies cast doubt on a causal explanation (Box 1).

One limitation of the studies to date assessing the effects of cannabis use on the adolescent brain is that they have focused on age (whereby onset of use before 15–17 years of age is considered ‘early’) rather than on adolescent pubertal markers or potential sensitive periods that may more accurately index stage of brain development\textsuperscript{55}. Since the eCB system interacts with gonadal hormones, and girls typically begin puberty earlier and reach pubertal maturation earlier than boys, pubertal stage may influence findings on sex differences. The few studies looking at acute effects of cannabis or Δ\textsuperscript{9}-THC have produced little in the way of age-dependent sex differences although chronic differences may exist\textsuperscript{25}. Younger age of regular cannabis use onset predicted poorer memory in women but not men\textsuperscript{56}. Surprisingly, the same study found earlier age of cannabis use initiation predicted better decision-making performance in both male and female cannabis users. Maturation of the PFC and its connections with the limbic system occurs earlier in girls\textsuperscript{57} and this difference may contribute to reported sex differences in the effects of adolescent cannabis use\textsuperscript{25, 56}. The paucity of studies of sex differences in the effects of cannabis limits conclusions and should be addressed by future research.
Effects persisting after stopping use. Several studies of long-term effects after an individual stops using cannabis are converging to show that cognitive impairments do not persist beyond 4–6 weeks after abstinence\textsuperscript{58, 59}. Using positron emission tomography (PET) imaging, one study\textsuperscript{30} demonstrated that chronic cannabis users showed a downregulation of cortical CB1Rs that correlated with years of use. After ~4 weeks of continuously monitored abstinence from cannabis at a secure research unit, their CB1R density returned to control levels, further supporting recovery within 4 weeks, and even, according one recent study, after as little as 2 days\textsuperscript{31}. Reversible downregulation of brain CB1Rs after chronic exposure to cannabis has also been shown in rodent studies\textsuperscript{60}. Other studies of ‘persisting’ effects have used structural and/or functional imaging but with cross-sectional designs, different abstention intervals and a range of confounds (including group differences in comorbid alcohol use and pre-cannabis level of functioning), which make it difficult to draw any causal conclusions. Longitudinal studies are thus needed to determine whether these effects of abstinence are seen even in those starting use in adolescence\textsuperscript{61}.

4. Cannabis addiction

Much research on cannabis and mental health has focused on psychosis (Box 2), although addiction is a far more common problem: we estimate that people who try cannabis are 9-fold more likely to become addicted to it than to develop psychosis in their lifetime\textsuperscript{62-64}. In this section, we introduce the concepts of cannabis addiction and withdrawal, review the rewarding effects of cannabinoids in relation to eCB, dopaminergic, opioid and noradrenergic neurotransmitter systems, and highlight vulnerability factors and possible treatments for cannabis addiction.
**Cannabis addiction and withdrawal.** The term ‘addiction’ is in a terminological quagmire; here, however, we define it as an acquired, chronic, relapsing disorder that is characterized by a powerful motivation to continually engage in an activity despite persistent negative consequences. Addictive drugs can all cause similar changes to brain circuits underpinning reward, salience, impulsivity, compulsivity, learning and memory\(^{39, 65-67}\) although these differ according to class of drug (including cannabis)\(^{68, 69}\). Clinical problems associated with cannabis use were previously diagnosed as ‘cannabis abuse’ or ‘cannabis dependence’ in the *Diagnostic and Statistical Manual for Mental Disorders, fourth edition, text revision (DSM-IV-TR)*. In the most recent version (*DSM-5*) these categories were amalgamated into a single diagnosis of ‘cannabis use disorder’ (CUD) as described in **Box 3**. The chances of becoming addicted to cannabis after lifetime exposure is 8.9%, which is comparatively lower than for cocaine (20.9%), alcohol (22.7%) or tobacco (67.5%)\(^{64}\). Nevertheless, the clinical need for treatment of cannabis addiction is substantial and increasing in North America, Europe and Oceania\(^5\). Across Europe, cannabis now accounts for more first-time entrants to drug treatment services than does any other illicit drug\(^{70}\).

A specific cannabis withdrawal syndrome – one aspect of addiction - is well recognized and affects around 50% of daily users upon cessation of use, and typically begins 1–2 days after cessation, peaks at 2–6 days and remits at 1–2 weeks\(^{71}\). Prominent symptoms include craving, sleep problems, nightmares, anger, irritability, dysphoria and nausea\(^72\). Cannabis withdrawal symptoms correlate with reductions in CB1R availability during acute abstinence\(^{31}\) and can be alleviated by \(\Delta^9\)-THC in a dose-dependent manner\(^{73}\). \(\Delta^9\)-THC withdrawal is associated with increased release of the stress peptide corticotropin releasing-factor (CRF) in the central nucleus of the amygdala\(^{74, 75}\). Similar increases in amygdalar CRF release are evident during withdrawal from most classes of recreational drugs (including nicotine, alcohol,
psychostimulants and opiates), and contribute to negative affective states and decreased brain reward function. It is therefore noteworthy that cannabis is frequently rolled with tobacco in ‘joints’ and many users also smoke cigarettes (Box 4). In daily users of cannabis and tobacco, individual withdrawal effects appear similar for both drugs; combined withdrawal produces stronger effects than does withdrawal for either one alone.

Cannabinoinds and reward. \( \Delta^9 \)-THC produces the effects cannabis users seek; they report liking it and wanting more. Additionally, cannabis with higher \( \Delta^9 \)-THC content (for example, 3.5% versus 2.0%) produces stronger reinforcement in human choice paradigms. Since reinforcement of drug use is considered to be one component in the transition from voluntary to compulsive use, these findings suggest that high-THC cannabis might increase vulnerability to addiction. However, it is difficult to extrapolate these findings to modern, high-potency cannabis with \( \sim 15\% \) \( \Delta^9 \)-THC. Recent naturalistic studies indicate that people adapt to rising \( \Delta^9 \)-THC concentrations by adding less cannabis to their joints and/or inhaling less smoke. Nevertheless, cross-sectional data suggest that use of high-THC forms of cannabis is associated with greater addiction severity. It is therefore possible that recent increases in cannabis potency might have contributed to the rising demand for treatment of cannabis addiction.

The presence or absence of CBD in evaluations of \( \Delta^9 \)-THC reward may also be relevant. One study found that people who smoked cannabis containing only low levels of CBD were more prone to have their attention captured by cannabis-related stimuli than were those smoking high-CBD cannabis. This suggests that CBD could protect against addiction, as attentional bias toward drug-related stimuli correlates with craving and is sensitive to relapse-provoking
manipulations. However, CBD does not influence the acute reinforcing effects of cannabis or the rewarding feeling of being ‘stoned’.

The rewarding effects of cannabinoids in animals depend on species, route of administration and experimental design. Rats will perform an operant behaviour to receive Δ⁹-THC infusions into the brain ventricular space and to receive CB₁R agonist infusions into the nucleus accumbens shell and posterior VTA, as with other drugs of abuse. However, there has been substantial difficulty in establishing operant intravenous Δ⁹-THC self-administration in rodents, possibly owing to the prolonged pharmacokinetic effects of Δ⁹-THC that impede establishment of discrete response–reward associations. The higher cognitive function in primates may allow for clearer discernment as to whether lever pressing behavior is causal for the somewhat delayed alterations in reward state resulting from intravenous Δ⁹-THC. It is also possible that the aversive and motor-depressant effects of Δ⁹-THC present greater impediments to self-administration in rodents than in primates.

Consistent with the human literature, studies in rats also demonstrate that Δ⁹-THC reward is dose-dependent. These effects appear to follow an inverted U-shaped curve whereby high Δ⁹-THC doses are less reinforcing than medium doses. For example, as indexed using the intracranial self-stimulation (ICSS) paradigm, reward system function in the rodent brain is enhanced by low doses of Δ⁹-THC, whereas higher doses and more-potent CB₁R agonists can decrease this function. Consistent with this, the rewarding effects of low doses of Δ⁹-THC or CB₁R agonists in the conditioned place-preference paradigm are supplanted by aversive effects at higher doses. An inverted-U shaped profile is consistent with data from human studies that indicate that high-THC cannabis is preferred and associated with greater addiction severity than low-THC cannabis whereas extremely potent products (such
as synthetic CB1R agonists) are less addictive than ‘natural’ cannabis, have more negative effects and are only preferred by 7% of users\textsuperscript{93}.

In animals, CB1R antagonism produces a ‘rightward’ shift along this inverse U-shaped reward–aversion dose-effect function, blocking the rewarding effects of low doses of CB1R agonists and preventing the aversive effects of high CB1R agonist doses. This underscores the bimodal effects of CB1R activity on brain reward processing. Squirrel monkeys voluntarily self-administer intravenous \( \Delta^9 \)-THC\textsuperscript{94} and rats reliably self-administer synthetic CB1R agonists\textsuperscript{95, 96} — actions that are prevented by CB1R antagonism. Taken together, these studies suggest that the CB1R activity has a crucial role in cannabinoid reinforcement and cannabis addiction.

Similar to \( \Delta^9 \)-THC and many synthetic cannabinoid agonists, eCBs exhibit agonist effects at brain CB1Rs. The eCB AEA takes its name from the Sanskrit word ‘ananda’, meaning ‘bliss’. Although pharmacologically enhanced eCB signalling (for example, through the inhibition of eCB clearance) generally does not produce rewarding effects \textit{per se}, persistent disruptions in eCB signalling appear to contribute to facets of drug dependence across drug classes\textsuperscript{97, 98}. CB1R downregulation in chronic cannabis users has been reported in three studies\textsuperscript{30, 31, 99}, these effects subside within days to several weeks of sustained abstinence\textsuperscript{30, 31}. Similarly, rodents chronically exposed to \( \Delta^9 \)-THC or synthetic CB1R agonists exhibit a reduction in CB1R function throughout the brain\textsuperscript{100, 101} that persists for days to weeks following \( \Delta^9 \)-THC treatment, followed by a functional recovery that varies between brain regions\textsuperscript{102}. eCB-mediated forms of synaptic plasticity in the nucleus accumbens and hippocampus are abolished following exposure to \( \Delta^9 \)-THC or CB1R agonists\textsuperscript{101, 103, 104} — and this may substantially impact reward processing and memory processes mediated by these regions. Chronic exposure to \( \Delta^9 \)-THC or CB1R agonists increases enzymatic clearance of AEA and reduces brain tissue AEA
content in rodents\textsuperscript{19,105,106}, and consistent with these data, frequent cannabis smokers exhibit decreased AEA levels in CSF\textsuperscript{107}. Although evidence is limited, elevated serum AEA levels may be evident in ex-users of the drug\textsuperscript{108}.

**Dopamine, opioids and noradrenaline.** Human PET studies indicate that \(\Delta^9\)-THC can increase dopamine release in the striatum\textsuperscript{109} although to a far lesser extent than do other recreational drugs, and not in all studies\textsuperscript{110}. In rodents, \(\Delta^9\)-THC and CB1R agonists increase the firing rate and bursting activity of VTA dopamine neurons, resulting in dose-dependent increases in the mesocorticolimbic release of dopamine\textsuperscript{111-113}. Conversely, withdrawal from chronic \(\Delta^9\)-THC or CB1R agonist exposure is associated with decreased firing of dopaminergic cells and decreased dopamine release in the nucleus accumbens\textsuperscript{114,115}. Consistent with these observations in animal models, reduced capacity to synthesize striatal dopamine was recently reported in human cannabis users, particularly among addicted individuals\textsuperscript{116}. However, in humans, chronic cannabis exposure is not typically associated with abnormalities in striatal dopamine release or in D\textsubscript{2} receptor expression\textsuperscript{117} and, together with the modest dopaminergic effects of acute \(\Delta^9\)-THC, the available human data provide only weak support for dopaminergic involvement in cannabis addiction.

\(\Delta^9\)-THC-induced increases in opioid peptide release\textsuperscript{118,119} may also contribute to the rewarding effects of cannabis. The opioid receptor antagonist naltrexone reduces \(\Delta^9\)-THC-induced increases in mesolimbic dopamine release, intravenous \(\Delta^9\)-THC self-administration and intracerebroventricular CB1R agonist self-administration in rats and monkeys\textsuperscript{120,121}. Sixteen days of naltrexone treatment reduced self-administration and some positive subjective effects of \(\Delta^9\)-THC in humans\textsuperscript{122}. 

Δ⁹-THC and other CB₁R agonists stimulate noradrenergic cell firing and increase levels of noradrenaline in multiple brain regions in which the neurotransmitter can impact motivated behaviours¹²³ — including the nucleus accumbens, prefrontal and cerebral cortices, hippocampus and hypothalamus¹²⁴-¹²⁶. The behavioural importance of CB₁R agonist-induced increases in noradrenaline release has not been carefully evaluated, although evidence suggests it may contribute to the aversive (but not anxiogenic) effects of high doses of CB₁R agonists¹²⁷. For example, the aversive effects of high doses of the CB₁R agonist WIN 55,212-2 (as measured in the conditioned place-aversion paradigm) are reduced by attenuation of noradrenergic signalling in the nucleus accumbens, although WIN 55,212-2-induced anxiety-like behaviour (as measured on the elevated plus-maze) is not reduced by these manipulations¹²⁷.

**Vulnerability factors.** Irrespective of the drug constituents⁸¹,⁸², only a minority of cannabis users become addicted; therefore, other factors must predict vulnerability. Concurrent tobacco use has been identified as a risk factor in a number of studies¹²⁸-¹³⁰, as have early adolescent onset and frequent (especially daily) use¹³¹ ¹²⁸. Males typically have an earlier opportunity to use cannabis, a greater risk of addiction and a faster progression from first opportunity of use to addiction⁶⁴, ¹²⁸, ¹²⁹. These findings are consistent with normative data from European treatment services: the mean age of first treatment is 24, the mean age at first cannabis use is 16 and 83% of treated individuals are male⁷⁰.

Interestingly, a 3-year prospective study of daily users found that variables related directly to cannabis use did not predict transition to addiction; more important were current factors such as living alone, coping motives and negative life events (such as having had a major financial crisis)⁸⁰. A meta-analysis of 24 twin studies¹³² suggested that genetic influences account for
55% of the vulnerability to cannabis addiction, with shared environmental factors and non-shared environmental factors accounting for much lower proportions (17.5% and 27.5%, respectively). Although isolated studies have identified specific gene variants associated with increased risk of developing cannabis use disorder (reviewed in ref. 133), cannabis addiction phenotypes are likely to be polygenic, and genotypes probably overlap with those linked to substance addiction in general134.

**Possible treatments for cannabis addiction.** Cannabis addiction is not easily treated by psychological therapies135, and although many pharmacotherapies, have been tested136 — including antidepressants, anxiolytics, noradrenaline-reuptake inhibitors, anticonvulsants, glutamatergic modulators and CB1R agonists — none has been approved. Based on existing clinical trial data, a 12-week trial of the GABA mimetic gabapentin137 and an 8-week trial of N-acetylcysteine138 have shown promise for reducing cannabis use according to urine sampling during treatment. Gabapentin also improved a number of secondary outcomes, including withdrawal symptoms, executive function and self-reported depression137. CB1R agonists such as dronabinol (oral synthetic Δ⁹-THC)139 and nabiximols140 (an oral spray containing Δ⁹-THC and CBD in equal ratio) attenuated cannabis withdrawal symptoms and improved treatment retention, but did not reduce cannabis use compared with placebo. These findings suggest that substitution treatments can replace Δ⁹-THC in cannabis but are not sufficient to promote abstinence from it.

Few studies have evaluated the contribution of dysregulated eCB signalling to cannabis addiction and related physiological and behavioural disruptions. However, eCBs provide important homeostatic regulation over emotional state141 and sleep function142, and so it is plausible that Δ⁹-THC-induced impairment of eCB signalling contributes to the negative
emotional states and sleep disturbances that are present during protracted cannabis abstinence\textsuperscript{71-73}. Intriguingly, studies in rodents demonstrate a palliative effect of 2-AG-clearance inhibitors on the somatic symptoms of CB1R-antagonist-precipitated $\Delta^9$-THC withdrawal\textsuperscript{105}. Collectively, these observations have led to the proposed use of eCB-clearance inhibitors as treatments for cannabis withdrawal, and perhaps addiction\textsuperscript{143,144}. Given the largely unmet clinical need, developing effective pharmacological treatments should be a top research priority.

**Cannabis, anxiety and depression**

Like most addictions, cannabis addiction is often comorbid with other mental health problems. Epidemiological evidence indicates a possible association between regular cannabis use and the development of anxiety and depression. However, the evidence is more mixed and less consistent than that between cannabis use and psychosis\textsuperscript{62}. One recent study compared the mental health of individuals who were addicted to cannabis (according to the *DSM-IV*) with that of non-addicted cannabis users who had similar patterns of cannabis use. Only the addicted users had depression and anxiety problems\textsuperscript{145}. Compared with general population norms, non-addicted frequent users were more likely to show externalizing disorders (such as attention-deficit hyperactivity disorder) that were likely to have predated their cannabis use. Otherwise, these individuals were similar in terms of mental health to the general population, suggesting that cannabis contributes to mental health problems only in those who are vulnerable for other reasons.

Depression and anxiety disorders not only are associated with cannabis addiction\textsuperscript{146} but also are predictive of whether individuals transition from use to addiction\textsuperscript{147}. Strikingly, a high number of cases of depression and anxiety disorders were reported among obese individuals who were treated with the anti-obesity drug Rimonabant, a CB1R antagonist. Many of these
individuals had no prior history of these disorders\textsuperscript{148, 149} and this led to the withdrawal of Rimonabant from therapeutic use. These findings suggest that CB1R antagonists increase the risk of depression and/or anxiety. Moreover, preclinical studies have shown that mice that genetically lack CB1Rs show increased depressive-like symptoms\textsuperscript{150} and, in wild-type mice, CBD has antidepressant effects\textsuperscript{151}. Rodent studies have implicated the eCB system in the regulation of emotion\textsuperscript{152}. Similarly, there are also data from rodent studies suggesting that impaired CB1R signalling leads to depression-like symptoms, and that enhancement of CB1R signalling produces antidepressant-like behavioural effects in rodents\textsuperscript{153}.

In our own studies of young (16–24-year-old) daily cannabis users, we have found that levels of $\Delta^9$-THC in hair are significantly associated with self-reported levels of both depression and anxiety\textsuperscript{154}. However, a recent epidemiological study\textsuperscript{146} suggested that increases in self-reported depression in cannabis users are not long-lasting, as no consistent associations were found between adolescent cannabis use and depression at age 29. By contrast, the same study showed daily cannabis use and cannabis addiction in early adulthood was associated with more than double the non-user control rate of anxiety disorders at 29. The association between cannabis use and anxiety may arise because the same factors that predispose people to use cannabis also predispose them to anxiety. Indeed, there is accumulating evidence that in vulnerable individuals, cannabis is often ‘used’ to self-medicate social anxiety\textsuperscript{155, 156}. This is interesting, as controlled studies of acute effects in humans have shown that $\Delta^9$-THC increases anxiety\textsuperscript{6}, whereas CBD decreases it\textsuperscript{6}. Furthermore, $\Delta^9$-THC and CBD acutely produce opposite but subtle effects on human facial affect recognition\textsuperscript{84} and amygdala activation when viewing fearful faces\textsuperscript{32}. 
The interconnectedness of cannabis use, mental health problems and cognitive functioning is important. It is inherently difficult to determine causality in the type of studies discussed above because factors besides cannabis use (e.g. premorbid cognitive and emotional function) may be directly associated with risk of mental illness. Such factors could predispose an individual both to mental illness and to using cannabis, and the combination of these disorders would in turn increase their impact upon cognitive functioning.

5. Conclusions and future directions

Cannabis has been used for thousands of years for a range of medicinal properties as well as for its desired psychological and social effects, which recreational users value. This use can, however, carry a penalty: a range of undesired effects that vary in the severity of their impact on the individual’s life. Although evidence of clear causality is lacking, these undesired effects may range from mild cognitive impairment to disabling psychiatric disorders. However, most recreational and medical users appear to rate the benefits as outweighing the risks in choosing to continue their cannabis use. It should be noted that public health messages to users are distorted, because funding for research is often targeted to studying the harmful effects of cannabis and ignores benefits. Despite studies aiming to document negative effects, occasionally positive effects are noted such as enhanced divergent thinking following either oral THC or smoked cannabis. Future research should evaluate perceived benefits to give a more balanced understanding; people clearly do not use cannabis only for its harms.

Throughout this article we have specified gaps in our knowledge. Although problems associated with cannabis use are mainly observed in heavy, frequent users, we are still not sure
what level of use of what type of cannabis is non-problematic. We need such data for harm-reduction advice for both medical and recreational users.

Another question that needs answering is: how does repeated use of cannabis causally affect the human adolescent and adult brain given that most cannabis users also use alcohol, another cognitively impairing drug? A recent comparison of daily cannabis users who also drank alcohol and alcohol-intake-matched, non-using controls in both adolescents and adults found no differences in brain structure between the two groups158, but longitudinal data are currently lacking. It is also still unclear exactly how the effects of cannabis vary across clinical populations. For example, a meta-analysis of showed that people who are diagnosed with schizophrenia and use cannabis function better cognitively than individuals with schizophrenia who do not use cannabis159. Finally, we need to understand more about how variants of the drug produce differential effects — variants not only in constituent cannabinoids but also the new synthetic cannabis variants (such as ‘spice’)93 as well as new forms of administration (for example, through vaping or edible forms)160.

Future studies will help to fill these gaps of knowledge, especially if they incorporate methodological improvements. Most studies of long-term effects assess level of cannabis use through various self-report measures (such as frequency, years of use, time to smoke a specific amount of the drug) and could benefit from improved biomarkers such as Δ⁹-THC and CBD levels in hair. We need longitudinal studies that follow young people from before puberty (that is, prior to drug use), through biologically defined puberty and into adulthood (while monitoring drug use) and again after subsequent abstinence or not. Such studies would use a comprehensive range of assessments (including: tests of cognition, motivation, brain function and mental health; biomarkers of different types; and quantities of cannabis or cannabinoids
and other recreational substances used) so the interactions among these factors may be monitored. This need should be addressed by the US National Institutes of Health-funded Adolescent Brain Cognition Development (ABCD) Study: a prospective, 10-year, longitudinal study of 10,000 individuals beginning at 9–10 years of age. This study is designed to assess the impact of substance use on brain development and neurocognitive function through a battery of measures obtained prior to cannabis use, following use at various levels and again following cessation of use. Given recent changes in the medical and legal status of cannabis in some countries, randomized controlled trials of the effects of different types and doses of cannabis can now be conducted. Work with animals will be important in delineating chronic effects, and studies administering doses and schedules within a human-relevant range (as exemplified in Ref. 47) are the most helpful.

The number of cannabis addicts may well grow as cannabis use becomes more acceptable and the drug more accessible. Indeed, there is evidence that this is already happening in the United States161. It is therefore urgent that we increase efforts to understand what factors influence the development of addiction and build preventative efforts against this. Currently, we lack an effective pharmacological treatment for cannabis addiction that can be used conjointly with psychosocial therapies to boost the current low efficacy of all treatment approaches. This need requires urgent research attention.

With hindsight, we can clearly see the enormous problems that have been caused to many individuals and to society by tobacco and alcohol. Unlike cannabis, these drugs are legal in most countries, despite the fact that, if asked to decide today which psychoactive drugs should be legal, cannabis (which rarely kills people) might well be judged as being comparatively benign. Legislative changes would help researchers, as current restrictive drug scheduling
markedly hinders neuroscience research and the innovation of psychiatric treatment. More importantly, if handled carefully from a harm-reduction standpoint, a regulated market might increase the control over the age of initiation of use and other vulnerability factors; inform accurately about dosage; and increase the availability of more-balanced cannabis (that is, with lower levels of Δ9-THC and higher levels of CBD) to maintain desired effects while reducing the incidence of harms.

References
31. This was the first study to report downregulation of CB1Rs in frequent cannabis users: the effects were reversed after 4 weeks of monitored abstinence, consistent with findings in rodents.
33. This paper reported a reversal of the downregulation of CB1Rs in frequent cannabis users after only 2 days.
36. This cross-sectional study used hair analysis to examine the relationship between cannabinoids and hippocampal integrity and found that chronic Δ9-THC exposure is associated with reduced hippocampal volume and N-acetylaspartate concentrations; however, these effects are not found in those with CBD as well as Δ9-THC in hair or after extended abstinence from the drug.

*This study provided proof-of-concept evidence in non-human primates that chronic exposure to exogenous cannabinoids during adolescence selectively disrupts cognitive processes that were actively developing during the time window of exposure.*

References 74 and 75 were the first to demonstrate Δ⁹-THC withdrawal is associated with increased levels of the stress neuropeptide CRF in the amygdala, which probably contributes to negative affective states and diminished brain reward function; this withdrawal-related effect is also common to many other classes of abused drugs, including nicotine, alcohol and opiates.

This comprehensive review considers the reinforcing effects and abuse liability of Δ⁹-THC and related cannabinoids as investigated in both human and animal studies.

References 103 and 104 were among the first to demonstrate that $\Delta^2$-THC exposure disrupts synaptic plasticity of nucleus accumbens neurons in rodents.

References 163 and 164 both examine associations between adolescent cannabis use and IQ by using data from large longitudinal cohorts in the United Kingdom and United States; both papers suggest there are non-causal explanations for the observed associations between adolescent cannabis use and lower IQ.

This is the largest study to date conducted on the acute response to cannabis and shows that psychotic-like symptoms in young healthy cannabis users are predicted by their AKT1 genotype, replicating the same effect observed in schizophrenia (see Refs 178 and 179).

180. Di Forti, M. et al. Proportion of patients in south London with first-episode psychosis attributable to use of high potency cannabis: a case-control study. The Lancet Psychiatry 2, 233-238 (2015). The risk of individuals having a psychotic disorder was roughly three-fold higher in those saying they used skunk (which contains high concentrations of Δ⁴-THC and negligible CBD) and five-fold higher in those reporting daily skunk use, compared with non-users; hash (which has a lower Δ⁴-THC content and more CBD) did not affect risk of a psychotic disorder.

181. Morgan, C.J. & Curran, H.V. Effects of cannabidiol on schizophrenia-like symptoms in people who use cannabis. The British Journal of Psychiatry 192, 306-307 (2008). The first study to show that psychosis-like symptoms are greater in those whose hair contains only Δ⁴-THC than in those whose hair contains both Δ⁴-THC and CBD or no cannabinoids — suggesting a protective effect of CBD.

Box 1. Does cannabis affect IQ or educational attainment?

Case-control and prospective cohort studies have found associations between cannabis use and both lower IQ and lower educational attainment. But do these associations reflect any causal relationships?

**Does cannabis affect IQ?**

To date, there have been three large prospective cohort studies that have assessed the relationship between cannabis use and IQ.

In a New Zealand birth cohort study of 1,037 38-year-olds born in 1972 or 1973, persistent cannabis dependence was associated with a decline of up to 6 IQ points from that measured at age 7-13 years\(^4^4\). The decline was particularly evident for those who developed cannabis dependence in adolescence, and remained apparent even for those who, at age 38 years, used cannabis less than once a week.

By contrast, a UK birth cohort study of 2,235 15–16-year-old adolescents born in 1991 or 1992 found that cumulative cannabis use was not associated with a lower IQ compared with non-using controls, once IQ measured pre-teen and various potential confounders (in particular, the adolescents’ use of cigarettes and alcohol) were accounted for\(^1^6^3\). Cannabis use was relatively low in this study, with only 72 adolescents reporting more than 50 lifetime cannabis exposures.

A US prospective cohort study of 3,066 17–20-year-olds found no difference in IQ change from that measured at age 9-12 years between monozygotic and dizygotic twins discordant for
cannabis use\textsuperscript{164}. However, there were only 47 discordant twin pairs in which the cannabis-using twin had used cannabis frequently (more than 30 cumulative uses, and/or daily use), limiting the strength of any conclusions from this study.

The UK and US studies therefore both suggest that genetic or environmental factors drive the observed associations between lower IQ and cannabis use, although both cohorts included younger participants with fewer cannabis exposures than did the New Zealand study.

To date, all studies have relied on retrospective self-report of cannabis use, have ignored possible residual effects of the drug on IQ test performance and have not addressed the potency or variety of cannabis used (see main article). Addressing these issues with confirmation of exposure to \(\Delta^2\)-THC and other cannabinoids (such as CBD) using hair samples from participants may lead to more reliable and consistent findings\textsuperscript{165}.

\textbf{Does cannabis use affect educational attainment?}

Several case-control and longitudinal studies have provided fairly consistent evidence of associations between adolescent cannabis use and both early school leaving and poorer educational performance\textsuperscript{166-169}. But the mechanisms producing these relationships remain hotly debated\textsuperscript{170}.

Causal explanations have posited that heavy cannabis use results in cognitive and/or motivational deficits, which in turn result in poorer educational attainment. Although there are many anecdotes about an ‘amotivational syndrome’ resulting from heavy cannabis use, a recent positron emission tomography study demonstrated that cannabis users had reductions in striatal dopamine synthesis that correlated with a measure of amotivation\textsuperscript{171}.

Alternatively, reverse causality has been also suggested; that is, perhaps poorer educational attainment leads to cannabis use\textsuperscript{166, 168}. However, the one study that addressed this hypothesis showed that the association between early school leaving and later cannabis use could be accounted for by cannabis use before leaving school early\textsuperscript{166}.

The other alternative is that educational attainment and cannabis use may not be causally related but instead share common risk factors\textsuperscript{168, 170, 172}. Reported associations between cannabis use and lower educational attainment have typically been robust to adjustment for some potential confounders such as early-life factors, baseline school performance or cognitive ability, social disadvantage and parental educational achievement)\textsuperscript{167, 169}. However, the
potential role of teenage behaviours that typically occur alongside cannabis use — including use of other substances and other ‘risky’ behaviours such as truancy — remain relatively unexplored\textsuperscript{163, 170}.

Recent analyses showed that adjusting for teenage use of other substances attenuated the association between cannabis use and school attainment\textsuperscript{163, 173, 174}. As such, the existence of unmeasured confounds is often posited to account for the negative associations with cannabis \textsuperscript{163, 168, 170}. Indeed, this idea is strongly supported by recent genetic studies that found no difference in early school leaving\textsuperscript{170} or years of education\textsuperscript{175} between both monozygotic and dizygotic twin pairs who were discordant for cannabis use\textsuperscript{170, 175}.

**Box 2 | Cannabis and psychosis: cause, consequence or correlation?**

Nearly 2,000 studies have been published on this topic since 1962, and the pro-psychotic effects of cannabis have dominated media reporting about this drug. But how clear is the link? A number of longitudinal, population-based studies show an earlier first episode\textsuperscript{176} and a roughly two-fold increase in risk of psychosis with regular cannabis use\textsuperscript{62}. Yet the vast majority of people who use cannabis do not develop psychotic disorders such as schizophrenia, and many people diagnosed with such disorders have never used cannabis.

More agreement is found in evidence that heavy cannabis use may mean that young people who are vulnerable to psychosis develop the disorder when they may not have otherwise done so. Converging data suggest that this may have a genetic basis, with certain polymorphisms of the gene encoding AKT1 potentially conferring risk of psychosis following smoking cannabis acutely\textsuperscript{177} and chronically\textsuperscript{178, 179}.

The type of cannabis used has recently been found to impact on risk of psychosis: self-reported hash use, even daily, is not associated with increased risk of psychosis, whereas self-reported daily use of skunk (which contains high levels of $\Delta^9$-THC and negligible amounts of CBD) is associated with a five-fold greater chance of having schizophrenia\textsuperscript{180}. Several studies using objective biological markers of use have shown that CBD reduces the psychosis-like effects of THC\textsuperscript{154, 181}.

How cannabis interacts with the brain to increase psychosis risk is unclear. One confusing finding is that of reduced dopamine release in cannabis users\textsuperscript{116}, which seems inconsistent with
the higher levels of dopamine release observed in people with psychosis. Disruptions in the brain’s endocannabinoid system, on the other hand, have been found in psychosis and may provide clues as to the pro-psychotic impact of cannabis. Higher levels of anandamide (AEA) in the cerebrospinal fluid have been associated with lower psychotic symptoms in individuals diagnosed with schizophrenia\textsuperscript{182}, in individuals classified as having prodromal schizophrenia\textsuperscript{183} who do not smoke cannabis and in cannabis users without a diagnosis of schizophrenia\textsuperscript{107}. AEA is known to have a neuromodulatory role in the brain; thus, during prodromal or first-episode psychosis, AEA may be increased to attempt to control dysregulated brain dopamine\textsuperscript{184}.

In addition, \textit{in vivo} positron emission tomography imaging and postmortem receptor autoradiography studies have consistently reported higher levels of ligand binding to cannabinoid 1 receptors in several cortical regions of people with schizophrenia\textsuperscript{185}. Whether these alterations are part of the disease pathology or a compensatory response remains unclear, but they do suggest a molecular basis for a heightened sensitivity to cannabis of individuals with schizophrenia, and perhaps of those at risk.

\section*{Box 3: ‘Cannabis use disorder’}

Cannabis related problems vary on a continuum and it is important to define these not only for clinical diagnosis and treatment but also for research. The \textit{Diagnostic Statistical Manual Edition, fifth edition (DSM-5)}\textsuperscript{186} has combined the definitions for ‘cannabis abuse’ and ‘cannabis dependence’ to provide criteria for the diagnosis of ‘cannabis use disorder’ (CUD). DSM-5 states that CUD is: “A problematic pattern of cannabis use leading to clinically significant impairment or distress, as manifested by at least 2 of the [symptoms from the three lists below], occurring within a 12-month period\textsuperscript{186}. Mild CUD is associated with having 2 or 3 of these symptoms, moderate CUD, with 4 or 5 symptoms, and severe CUD, with 6 or more symptoms.

One advantage of combining abuse and dependence criteria in CUD is to provide a clearer continuum between mild and severe, because previously all cases of dependence also met criteria for abuse. Another advantage is that dependence is often a normal bodily response to a substance (for example, a prescribed pain killer) which should not to be confused with addiction (insomuch as stopping use of that pain killer does not necessarily lead to drug-seeking).
The following symptoms were included from *DSM-IV* criteria for cannabis dependence:

- Cannabis is often taken in larger amounts or over a longer period than was intended
- There is a persistent desire or unsuccessful efforts to cut down or control cannabis use
- A great deal of time is spent in activities necessary to obtain cannabis, use cannabis, or recover from its effects
- Important social, occupational, or recreational activities are given up or reduced because of cannabis use
- Cannabis use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by cannabis
- Tolerance, as defined by either [1] a need for markedly increased cannabis to achieve intoxication or desired effect or [2] a markedly diminished effect with continued use of the same amount of the substance
- Withdrawal, as manifested by either [1] the characteristic withdrawal syndrome for cannabis or [2] cannabis is taken to relieve or avoid withdrawal symptoms

The following symptoms were included from *DSM-IV* criteria for cannabis abuse:

- Recurrent cannabis use resulting in a failure to fulfil major role obligations at work, school, or home
- Continued cannabis use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of cannabis
- Recurrent cannabis use in situations in which it is physically hazardous

This item was added as a new symptom to DSM-5:

- Craving, or a strong desire or urge to use cannabis

One *DSM-IV* criterion — concerning persistent legal problems related to cannabis use — was dropped and not included in *DSM-5* because it largely reflected sociocultural factors to do with policing and law enforcement rather than cannabis use factors.
**Box 4: The gateway theory**

Although cannabis is traditionally considered as a ‘soft’ drug, it is widely believed to act as a ‘gateway’ to harder drugs such as cocaine or heroin (with harm defined in terms of detrimental effects of using that substance on the individual and on society). According to this theory, there is a sequential progression from one drug to the next (for example, cannabis leading to cocaine, and then heroin)\(^{187}\). This theory rests on evidence that use of one drug increases the likelihood of using the next drug in the ‘sequence’, which may be interpreted as causal if all other confounds are accounted for\(^{187}\).

Evidence does support sequence and association between cannabis and other illicit drugs, and these effects increase with frequency of cannabis use and adolescent onset\(^{188}\). Additionally, a twin study\(^{189}\) suggested that these effects cannot be attributed to shared genetic or environmental factors alone. Studies in rats demonstrate that adolescent Δ⁹-THC exposure results in increased opiate consumption and facilitated learning of cocaine self-administration in adulthood\(^{190-192}\), and that the influence of adolescent Δ⁹-THC exposure on opiate reward may be transgenerational\(^{193}\).

Establishing causality remains challenging, however, and putative mechanisms remain speculative. For example, one possibility is that the wide availability of cannabis means people are more likely to use it first and this increases the chances that other illicit drugs are used because of contact with other drug users and with people selling illicit drugs\(^{189}\). This formed part of The Netherlands’ rationale for the regulated sale of cannabis; incidentally, the rates of cocaine use among people who have used cannabis are lower there (22%) than in the United States (33%)\(^{194}\).

Biological explanations for the gateway hypothesis are supported by evidence that exposure to THC enhances the reinforcing effects of other drugs. Intriguingly, however, prior Δ⁹-THC ingestion increases rats’ self-administration of nicotine and the reinforcing effects of nicotine\(^{195}\), but this does not occur with prior cocaine or heroin exposure\(^{196, 197}\). Indeed, one of the most potentially harmful and underappreciated effects of cannabis is the ‘reverse gateway’: by smoking tobacco together with cannabis in ‘joints’, individuals may progress to nicotine addiction\(^{160, 198}\).
Figure 1 | Cannabinoid 1 receptor distribution within reward-, habit- and cognition-related circuits. A simplified conceptualization of the major circuits implicated in reward (namely, the ventral tegmental area (VTA), nucleus accumbens and ventral pallidum (VP)), stimulus–response habit formation (the dorsolateral striatum (dlStr) and globus pallidus (GP)) and cognition (the prefrontal cortex (PFC), hippocampus (HIPP), and amygdalar regions). Among these regions, CB1Rs are expressed with the following order of density: HIPP ≈ basolateral amygdala (BLA) ≈ PFC > VP ≈ GP > DSTr > NAc > VTA ≈ bed nucleus of the stria terminalis (BNST) > central nucleus of the amygdala (CeA). Within the amygdala, CB1R expression is highest in the lateral and basolateral nuclei, with substantially lower expression in the central nucleus. In the dorsal striatum there is a comparable medial–lateral gradient of CB1R expression with greater levels of expression evident in lateral aspects, and comparatively lesser CB1R expression is observed in the NAc. The dense CB1R expression in HIPP, PFC and amygdalar regions underlies the effects of cannabis and CB1R agonists on cognitive and memory function, whereas the CB1R presence within the mesocorticolimbic regions (VTA, NAc, PFC) contribute to the rewarding effects produced by cannabinoids.

Figure 2 | Effects of acute or chronic exposure to cannabis on reward- and cognition-related circuits. Graphical summary of alterations in neurobiological function resulting from chronic cannabinoid agonist exposure based on studies in rodents, non-human primates and humans. These collected observations should be viewed as a model of chronic cannabis exposure, rather than an explicit representation of cannabis-induced alterations in human brain function. a | Acute cannabis or moderate-dose CB1R agonist exposure induces neurochemical events in the mesolimbic system similar to those produced by other drugs of abuse, including increased dopamine (DA) release and an attenuation of evoked GABA and glutamate (Glu) release in the nucleus accumbens. The induced increase in opioid peptide release in the NAc probably also contributes to the acute rewarding effects of Δ9-THC. Disruptions in cognitive function (including attention and memory impairments) probably result from: decreased acetylcholine (ACh) release in hippocampus (HIPP) and prefrontal cortex (PFC); reduced GABA release and increased Glu release in the PFC; and increased noradrenaline (NA) release in HIPP and frontal cortical areas. b | Chronic Δ9-THC or CB1R agonist exposure results in decreased CB1R expression and function in many brain regions. Positron emission tomography imaging of daily cannabis users has revealed considerable decreases in CB1R levels, particularly in cortical regions, that correlate with
years of cannabis use and withdrawal, and rapidly normalise during abstinence\textsuperscript{30, 31}. Rodent studies demonstrate regional differences in the effects of chronic $\Delta^9$-THC on CB1R expression and function, with rapid and profound decreases evident in the hippocampus and layer VI of frontal cortex, smaller but still statistically significant decreases in striatal and amygdalar regions, and nonsignificant disruptions in regions such as the globus pallidus (GP) and hypothalamic nuclei\textsuperscript{100, 101}. The pronounced deficits in cortical and hippocampal CB1R function are consistent with memory and cognitive impairments associated with chronic cannabis use in humans. In this regard, chronic adolescent $\Delta^9$-THC exposure results in persistent disruptions of the hippocampal and cortical signalling that is critical for proper memory and cognitive functions. Chronic $\Delta^9$-THC exposure also disrupts reward-related signalling mechanisms in the mesolimbic system by reducing DA cell density in the ventral tegmental area (VTA)\textsuperscript{210} and by decreasing VTA DA cell firing and DA release in the NAc during both spontaneous and CB1R antagonist-precipitated withdrawal\textsuperscript{114, 115}. Consistent with these observations in animal models, reduced striatal DA synthesis has been observed in human cannabis users, and this effect appears to be driven by individuals meeting cannabis use disorder criteria\textsuperscript{116}. Together with increased stress-related signalling, such as dynorphin release in the NAc\textsuperscript{211} and corticotropin releasing factor release in the amygdala\textsuperscript{74, 75}, these deficits in mesostriatal DA function may contribute to negative affective states associated with THC abstinence. Adolescent $\Delta^9$-THC exposure also results in persistent increases in opioid peptide gene expression and influences the mesolimbic system of rats\textsuperscript{191, 212, 213}, possibly contributing to an increase in the rewarding effects of opiates and increase opiate by these animals in adulthood\textsuperscript{190-192, 212}.

GLOSSARY

Cannabis abuse
Cannabis use that is problematic for various aspects of an individual’s life, (for example, causing occupational, educational, or social problems), or that is carried out in dangerous contexts.

Cannabis dependence
A group of severe consequences of repeated cannabis use, including tolerance to effects, withdrawal symptoms upon cessation, dysregulation of use, increased involvement with cannabis at the expense of other activities, and continued use despite the problems it causes.

Conditioned place-preference (CPP) procedure
Pavlovian conditioning procedure used to index the motivational properties of drug experience. Typically, the different in time spent in an environment associated with drug intoxication is compared with that spent in a neutral context.
**Episodic memory**
Personal, contextualised autobiographical memory of past experiences.

**Intracranial self-stimulation (ICSS)**
An operant paradigm in which animals perform a behavioural response to receive brief electrical pulses into specific regions in the brain reward pathways.

**Working memory**
The capacity to hold information ‘online’ (maintenance) and manipulate it.

**Long-term depression**
(LTD). An enduring decrease in the strength of neurotransmission at a synapse, implicated in learning and memory.

**Long-term potentiation**
(LTP). An lasting increase in the strength of neurotransmission at a synapse, implicated in learning and memory.

**Psychosis**
A mental disturbance characterized by aberrant perceptions (hallucinations) and thoughts (delusions) that causes an individual to lose touch with external reality.

**Reinforcement**
A learning process through which particular stimuli or events (such as familiar drug-taking environments, or pleasant drug effects) influence the likelihood or strength of behaviour, such as drug seeking.

**Biographies**

**H. Valerie Curran** is currently Professor of Psychopharmacology at University College London, Director of the UCL Clinical Psychopharmacology Unit (CPU) and Clinical Research Lead at local London Drug Services. Her research, mainly funded by the UK Medical Research Council, focuses on: neurobiological, neurocognitive and emotional factors in substance use disorders; the development of novel treatments for addictions; and individual resilience and vulnerability factors in substance use disorders. The CPU website is: [http://www.ucl.ac.uk/cpu](http://www.ucl.ac.uk/cpu)

**Tom P. Freeman** is a postdoctoral research associate at University College London where he is coordinating a clinical trial for the treatment of cannabis addiction, funded by the UK Medical Research Council. His research interests include: contrasting the harmful and
beneficial effects of different cannabinoids; the relationship between addiction and psychosis; and using experimental medicine to inform novel treatments for mental health problems.

**Claire Mokrysz** is currently a UK Medical Research Council Ph.D. student in psychopharmacology at University College London. Her interests include the neurocognitive effects of recreational drug use and the identification of vulnerability factors associated with an increased risk of drug-related harm. Her research currently focuses on whether adolescence represents a period of heightened vulnerability to the potential harms of cannabis and alcohol use.

**David A. Lewis** is the Thomas Detre Professor and Chair of the Department of Psychiatry at the University of Pittsburgh. His research interests focus on the functional architecture and development of the primate prefrontal cortex, and the alterations in this circuitry associated with schizophrenia and adolescent cannabis exposure.

**Celia J. A. Morgan** is Professor of Psychopharmacology at the University of Exeter. Her work focuses on translational approaches to the discovery of new pharmacological and psychological treatments for addiction and other psychiatric disorders. The UK Medical Research Council funds her main research.

**Loren H. Parsons** received his Ph.D. in chemistry from Emory University in Atlanta, Georgia, USA followed by postdoctoral training in behavioural pharmacology and neurochemistry at The Scripps Research Institute (TSRI) in La Jolla, California, USA. He is currently Professor in the Committee on the Neurobiology of Addictive Disorders at TSRI, Director of the TSRI Alcohol Research Center and Director of the Ruth L. Kirchstein Training Program at TSRI. His research looks into the neurobiological bases of addiction, with particular focus on the role of dysregulated endocannabinoid signaling in drug dependence and protracted withdrawal, and the cortical mechanisms underlying dependence-related cognitive impairment. The Parsons lab website is: http://www.scripps.edu/parsons/Research.html.

**Key Points:**

- Cannabis contain over 100 unique ingredients we call ‘cannabinoids’, and the proportions of these vary widely across different strains of the plant. High-delta-9-tetrahydrocannabinol (Δ9-THC) varieties with negligible levels of cannabidiol (CBD) now dominate many Western markets and are more harmful than lower-Δ9-THC, higher-CBD varieties.
Like other recreational drugs, Δ9-THC increases release of dopamine and opioid peptides (in preclinical studies) and alters endocannabinoid processing in the mesocorticolimbic reward system. Long-term Δ9-THC exposure leads to a downregulation of brain cannabinoid receptor function that reverses following abstinence.

People who try cannabis are nine-fold more likely to become addicted to it than to develop psychosis. Cannabis addiction is an increasing problem globally and no effective pharmacological treatments currently exist — this remains a major unmet clinical need.

The association between cannabis use and psychosis can be influenced by a number of vulnerability factors, including genetics, environmental factors and the frequency and type of cannabis used. Evidence linking cannabis use with the development of depression and anxiety is less consistent, although these disorders are often comorbid with cannabis addiction.

The acute effects of cannabis upon cognitive function are well documented and the most robust, dose-related decrements are to working and episodic memory. Its long-term cognitive effects remain controversial, are influenced by many confounds and appear to subside a month after stopping use of the drug.

We should ensure that global legislative changes are informed by neuroscience and public health. They should mitigate against adolescent uptake and the availability of highly potent products, including synthetic agents such as ‘spice’, that act as full cannabinoid receptor agonists.

The authors declare competing interests: see Web version for details.

Conflicting interests statement
C.J.A.M. has been a consultant for Janssen and GlaxoSmithKline. D.A.L. currently receives investigator-initiated research support from Pfizer and in 2012–2014 served as a consultant in the areas of target
identification and validation and new compound development for Autifony, Bristol-Myers Squibb, Concert Pharmaceuticals and Sunovion. There are no other conflicts of interest to declare. [Au: Edits OK?]
