ABSTRACT

This study of mid-Cretaceous foraminifera from the Linzhou, the Coqen and the Xigaze Basins in the southern Tibetan Plateau has provided the first high resolution biostratigraphic
description of these limestones and interpretation of their paleoenvironmental settings. The fossil assemblages are dominated primarily by orbitolinid larger benthic foraminifera. We reassessed the identification of many taxa, dividing the South Tibetan sedimentary successions of Aptian to Early Cenomanian age into eight new foraminiferal biozones (TLK1a–h): (i) (TLK1a) a shallow reefal environment corresponding to planktonic foraminifera zone (PZ) Aptian 1–2, dominated by *Palorbitolina* and *Praeorbitolina* spp.; (ii) (TLK1b) a transgressive, reefal to forereefal environment corresponding to PZ Aptian 3, characterized by the first appearance of *Mesorbitolina parva*; (iii) (TLK1c) a shallow reefal to backreef environment of Late Aptian (PZ Aptian 4) age, characterised by the first appearance of *Mesorbitolina texana*; (iv) (TLK1d) a transgressive phase of forereef to an inner neritic environment of Albian (PZ Albian 1) age, characterised by the first appearance of *Cuneolina pavonia*; (v) (TLK1e) an open-marine reefal environment of Albian (PZ Albian 2) age, with assemblages dominated by flat to slightly conical orbitolinids, characterized by the first appearance of *Palorbitolinoides hedini*; (vi) (TLK1f) a shallow, open-marine reefal to forereef environment of Middle Albian (PZ Albian 3) age, dominated by flat and convex orbitolinids, and characterised by the first appearance of *Mesorbitolina aperta*; (vii) (TLK1g) a reefal to forereef environment of end Albian (PZ Albian 4) age, characterized by the appearance of *Conicorbitolina* cf. *cuvillieri* and *Pseudochoffatella cuvillieri*, and in which Early Aptian species of *Praeorbitolina* cf. *wienandsi* have been recorded for the first time from the Late Albian; (viii) (TLK1h) a shallow reefal environment of Early Cenomanian age characterized by the first appearance of *Conicorbitolina* sp. A and *Nezzazata conica*. The eight new biozones provided biostratigraphic correlation of the Langshan, Sangzugang and Takena Formations in the Lhasa terrane, while the observed evolution of the environmentally controlled microfacies corresponds closely with the current, inferred global
sea-level variation of the period. The almost continuous sedimentary sequences studied allowed previously defined orbitolinid phylogenetic linages to be confirmed.

INTRODUCTION

What is now southern Tibet was, in the mid-Cretaceous (93–126 Ma), paleogeographically located at the southern margins of the Asian Plate boarding the eastern Tethyan Ocean. It was the site for the deposition of large volumes of sub-tropical backreef and reefal, shallow-marine carbonates. The variations in foraminiferal assemblages, in particular the larger benthic foraminiferal (LBF) assemblages, hold the key to date the age of the mid-Cretaceous limestones in southern Tibet and to understand the paleoenvironmental and tectonic development of the region. At this time, the LBF assemblages of the region were dominated mainly by the agglutinated orbitolinids.

Although studies of the mid-Cretaceous Tibetan orbitolinids have been reported over the last four decades (e.g., Zhang, 1982, 1986, 2000; Smith & Xu, 1988; Yin et al., 1988; Zhang et al., 2004) from isolated occurrences, their detailed biostratigraphy is not available. Also, the taxonomy and identification schemes used in that literature are often not compatible with the now widely accepted description of orbitolinids (see Schroeder et al., 2010).

In this study, we describe orbitolinid-rich assemblages from largely continuous sedimentary sequences from the Lhasa terrane of the southern Tibetan Plateau, which range in age from Early Aptian to Early Cenomanian. Material from the Sangzugang Formation from the Xigaze Basin, the Takena Formation in the Linzhou Basin, the Langshan Formation in the Coqen Basin were analysed in this study (Fig. 1).
GEOLOGICAL SETTING

The Tibetan Plateau (Fig. 1) comprises a series of terranes, including (from north to south) the Songpan-Ganzi complex, the Qiangtang terrane, and the Lhasa terrane (Yin & Harrison, 2000). The Lhasa terrane, located on the southern part of the Tibetan Plateau, is bounded by the Yarlung-Zangbo suture zone with the Tethyan Himalaya to the south, and by the Bangong-Nujiang suture zone with the Qiangtang terrane to the north (Yin & Harrison, 2000; Zhu et al., 2013). The Lhasa terrane is divided into southern, central and northern subterranes, which are separated by the Luobadui-Milashan Fault (LMF) and the Shiquan River-Nam Tso Mélange Zone (SNMZ), respectively (Zhu et al., 2011, 2013).

The southern Lhasa subterrane is comprised of the Gangdese magmatic arc and Xigaze forearc basin. The Gangdese magmatic arc is characterized by Late Triassic-Early Paleogene Gangdese batholiths and Paleogene Linzizong volcanic rocks, with minor sedimentary cover (Chu et al., 2006; Ji et al., 2009; Zhu et al., 2013). The Xigaze forearc basin, located in the south of the Gangdese arc (Fig. 1), is dominated by the thick Albian-Campanian deep-water turbidites and thin shallow-marine Sangzugang limestones (Dürr, 1996; Wang & Liu, 1999; Wang et al., 2012; An et al., 2014). The Sangzugang Formation, exposed discontinuously from Sangzugang village in Sagya County to the Xigaze airport, consists of thick-bedded or massive dark-gray bioclastic limestones with abundant benthic foraminifera, rudists and corals, and minor occurrences of bivalves. The 60–230 m thick unit is in fault contact with either the overlying deep-water turbidites or the post-collisional Gangrinboche conglomerate (Wang et al., 2013), and its original stratigraphic relationships are uncertain. The Sangzugang Formation was deposited in reefal environments along the northern part of the forearc basin during the Late Aptian to Early Albian (Liu et al., 1988).
The Linzhou basin lies at the retro-side of the Gangdese arc, and is filled by Jurassic to Cretaceous volcanic, carbonate and terrigenous clastic rocks that are overlain by the Paleogene Linzizong volcanic successions (Pan et al., 2004). The Early Cretaceous Takena Formation in this basin is intercalated between the underlying shore-face Chumulong Formation and the overlying fluvial Shexing Formation (Leier et al., 2007). Orbitolinid-bearing limestone beds occur in the middle of the Takena Formation. Samples from two sections (the Jiarong and Laxue sections) were studied.

In the central Lhasa subterrane, Carboniferous metasedimentary deposits, Permian limestones, Jurassic siliciclastic deposits and abundant Cretaceous magmatic and sedimentary rocks are widespread in many places. In our study area (Fig. 1), thick (up to several km) Cretaceous sedimentary strata are exposed (Pearce & Mei, 1988; Harris et al., 1990; Zhu et al., 2009, 2011). These strata are composed of the Lower Cretaceous Duoni sedimentary-volcanic rocks, the Langshan limestone, and Upper Cretaceous Daxiong continental molasse (Leeder et al., 1988; Yin et al., 1988; Zhang 2000, Zhang et al., 2004; Sun et al., 2015). The Langshan limestone, upon which this study focused, is exposed in a west-east direction with an extend of up to ~1000 km in the central Lhasa subterrane, and is bounded by the Gangdese magmatic arc to the south and Shiquan River-Nam Tso Mélange Zone Gaize-Selin Co thrust (SNMZGST) to the north (Zhang, 2000; Zhang et al., 2004; Kapp et al., 2007).

LITHOSTRATIGRAPHY AND SAMPLING

The Sangzugang Formation in the Xigaze Basin is 60 to 230 m thick (Fig. 2), and it outcrops near the northern boundary of the Xigaze forearc basin (Wang et al., 2012; An et al., 2014). Based on foraminiferal data, the Sangzugang section (GPS: 29°18'11.1"N;
88°24′51.3″E) has been dated as Aptian–Albian in age (Cherchi & Schroeder, 1980; Bassoullet et al., 1984).

In the Linzhou basin, the Penbo Member of the Takena Formation (Yin et al., 1988; Leier et al., 2007) consists of about 250 m of mudstone, siltstone and limestone with overlying successions of fluvial red beds of the Shexing Formation. Previous studies placed the Takena limestones as Aptian–Late Albian based upon the study of echinoids, ammonoids and foraminifera (Yin et al., 1988). In this study, we measured and sampled the limestone-bearing strata (a ~100 m thick middle part of the Takena Formation) from two sections (the Jiarong section, 29°53′48.7″N, 91°19′19.1″E; and the Laxue section, 29°54′25.1″N, 91°20′48.1″E). Detailed lithostratigraphic logs and sample positions are shown in Figure 3.

In the Coqen Basin, the Langshan limestone (Fig. 1) unconformably overlies volcanic rocks of the Lower Cretaceous Zelong Group or conformably overlies the Duoni Formation (see Sun et al., 2015), and is mainly composed of ~80–800 m of orbitolinid-bearing wackestones and packstones (XZBGM, 1993; Zhang et al., 2004; Scott et al., 2010). Three sections of mid-Cretaceous Langshan limestones were measured and sampled for this study. The Langshan Formation in the Azhang section (31°56′48.5″N, 84°55′16.5″E) consists of ~800 m of orbitolinid-rich limestones (Fig. 4), while the Langshan Formation in the Guolong section (31°26′23.6″N, 85°24′46.6″E) reaches ~400 m in thickness (Fig. 5), and the Xiagezi section (31°10′52.0″N, 84°52′14.0″E) consists of ~80 m of orbitolinid-bearing wackestones and packstones (Fig. 6).

In total, our study is based on a detailed analysis of over 350 samples from six logged stratigraphic sections (see Figs. 2–6). Analyses of these samples allowed us to review the mid-Cretaceous Tibetan benthic foraminiferal assemblages and to revise their stratigraphic range, while tracing their phylogenetic and paleoenvironmental evolution, which correlates well with the current inferred global sea-level variation of the period (Fig. 7). The occurrence
of planktonic foraminifera (PF) at some levels of the sections allowed us to constrain the ages of these LBF and to confirm the dating of the formations.

TIBETAN ORBITOLINIDS: TAXONOMY, PHYLOGENETIC EVOLUTION AND BIOZONATION

During the deposition of the mid-Cretaceous sediments of the Takena, Langshan and Sangzugang Formations, agglutinated foraminifera made up the bulk of the foraminiferal assemblages, while PF were sporadic, only occurring at a few levels. Small biserial/triserial textularids, conical cuneolinids (e.g., *Cuneolina*, *Vercorsella*, *Sabaudia*) and planispiral forms (e.g., *Pseudocyclammina*) are common. However, the major components of these formations are the flat to broadly conical orbitolinids.

The orbitolinids are characterized by conical tests that are usually a few millimetres in height and diameter (although they can attain diameters of 5 cm or more). In axial section, the embryo is located at the apex of the cone, followed by series of discoidal chamber layers. In transverse section, the chambers are seen divided into a marginal zone, with subepidermal partitions and a central zone with radial partitions. The radial partitions in *Orbitolina* thicken away from the periphery and anastomose in the central area, producing an irregular network. The earliest formed chambers of the megalospheric generation can form a complex embryonic apparatus that can be divided into a protoconch, deutoconch, a subembryonic zone and periembyronic chamberlets depending on the genera involved. For instance, in *Palorbitolina*, the embryonic apparatus consists of a large, globular, fused protoconch and deutoconch, followed by periembyronic chambers. *Praorbitolina* evolved an embryonic apparatus divided into a protoconch and deutoconch with an incompletely divided subembryonic zone. In *Mesorbitolina*, the deutoconch and subembryonic zone are more or
less of equal thickness. In Conicorbitolina the marginal zone becomes extensively divided by vertical and horizontal partitions, while in Orbitolina the deuteroconch is highly subdivided and of much greater thickness than the subembryonic zone (Fig. 8) (see Schroeder, 1975; Hottinger, 1978; Simmons et al., 2000; BouDagher-Fadel, 2008; Schroeder et al., 2010).

During this study, we have had cause to redefine many of the orbitolinid species previously defined by Zhang (1982, 1986, 1991) from Xainsa, Baingoin and western Tibet as synonyms of previously established species. Some of Zhang’s species were revised by Rao et al. (2015). We here identify the following:

**SYSTEMATIC PALEONTOLOGY**

Order FOAMINIFERIDA Eichwald, 1830

Superfamily ORBITOLINOIDEA Martin, 1890

Family ORBITOLINIDAE Martin, 1890

Genus Palorbitolina Schroeder, 1961

Type species: *Madreporites lenticularis* Blumenbach, 1805

*Palorbitolina lenticularis* (Blumenbach, 1805)

*Madreporites lenticularis*, Blumenbach, 1805 p. 80, figs 1–6.

*Orbitolina (Palorbitolina) discoidea* Gras, Zhang, 1982, pl. 8, figs. 1–10, pl. 7, fig. 10.

*Orbitolina (Palorbitolina) umbellata* Zhang, 1982, pl. 7, fig. 15

*Orbitolina (Palorbitolina) complanata* Zhang, 1982, pl. 8, figs. 13–17, pl. 9, figs. 1–7

*Discussion*: *Palorbitolina lenticularis* is characterised by an annular periembryonic zone completely surrounding the upper part of the centric embryonic chamber. It was
described as *O. (P.) umbellata* and *O. (P.) complanata* from the Aptian of Takena Formation in Xizang, China.

**Distribution:** This species is found in this study in the Aptian (PZ Aptian 1–4a, TLK1a–early part of TLK1c) in Jiarong, Laxue, Azhang and Guolong sections and in the Linzhou basin.

Genus *Mesorbitolina* Schroeder, 1962

Type species: *Orbitulites texanus* Roemer, 1849

*Mesorbitolina birmanica* (Sahni, 1937)

Fig. 9.10

*Orbitolina birmanica* Sahni, 1937, p. 368, pl. 30, figs 1–19.

*Orbitolina (Mesorbitolina) birmanica* Sahni, Zhang, 1986, p. 112, pl.5, figs. 1–2.

*Orbitolina (Orbitolina) deltoides* Zhang, 1982, p. 73, pl. 12, fig.7.

**Discussion:** *M. birmanica* is characterised by a biconvex embryonic apparatus, which includes a plano-convex protoconch and a deutoconch that is irregularly subdivided by occasional partitions. Zhang (1982) described *O. (O.) deltoids*, which is similar to *M. birmanica*, as new species from the lower Cretaceous of the Lhasa Block of Tibet.

**Distribution:** In this study, *M. birmanica* was found in the Aptian to Albian (PZ Aptian 4–Albian 4, TLK1c–g) of Azhang, Guolong sections and in the Coqen basin.

*Mesorbitolina lotzei* Schroeder, 1964

*Orbitolina (Mesorbitolina) lotzei* Schroeder, 1964, p. 469, text-fig. 3a–f.

*Orbitolina (Columnorbitolina) tibetica* Cotter, Zhang, 1982, pl.2, figs. 7–16.
Discussion. This species is characterised by a centrally positioned embryo, laterally surrounded by an annular first postembryonic chamber. Zhang (1982) illustrated similar forms from the lower Cretaceous of the Lhasa Block of Tibet under his new genus and identified them as *Orbitolina (Columnorbitolina) tibetica* Cotter. Here these species are considered as synonyms of *M. lotzei*.

Distribution: This species is here found in Aptian age (PZ Aptian 2, upper part of TLK1a) sections of Jiarong and Laxue, and in the Linzhou basin.

*Mesorbitolina parva* (Douglas, 1960)

Figs. 10.1, 10.3

*Orbitolina parva* Douglas, 1960, p. 39, pl. 9, figs. 1–14.

*Orbitolina (Columnorbitolina) lhuenzhubensis* Zhang, 1982, p. 74, pl. 3, figs. 6–9.

*Orbitolina (Columnorbitolina) minuscula* Zhang, 1982, pl. 6, figs. 5–9.

*Orbitolina (Columnorbitolina) scitula* Zhang 1982, p. 64, pl. 4, figs. 6–12.

*Orbitolina (Columnorbitolina) absidata* Zhang, 1986, p. 109, pl. 2, figs. 13–17.

Discussion: This species is characterised by a deutoconch showing a complete system of radial partitions. Zhang (1982) and (1986) described and illustrated similar forms as new species: *O. (C.) lhuenzhubensis, O. (C.) minuscula* and *O. (C.) scitula* from the Aptian of Takena Formation in Xizang, China; *O. (C.) absidata* and *M. irregularis* from the Aptian of the Lhasa Block, Tibet.
**Distribution:** This species was found in Aptian sections (PZ Aptian 3–4a, TLK1b–TLK1c) of the Azhang, Guolong and Xiagezi in the Coqen basin.

_Mesorbitolina texana_ (Roemer, 1849)

Figs. 10.2, 10.4–10.5

*Orbitulites Texallus* Roemer, 1849, p. 392.

*Orbitulites Texallus* Roemer, Roemer, 1852, p. 86, figs. 7a–d.

_Mesorbitolina maryoensis_ Zhang, 1982, p.111, pl. 4, figs. 1–6.

*Orbitolina* (*Palorbitolina*) _megasphaerica_, Zhang, 1982, p. 69, pl. 8, fig. 11.

*Orbitolina* (*Columnorbitolina*) _orientala_ Zhang, 1982, p. 65, pl. 6, figs. 1–4.

*Orbitolina* (*Columnorbitolina*) _pengboensis_ Zhang, 1982, p. 74, pl.3, figs. 1–5.

*Orbitolina* (*Columnorbitolina*) _rutogensis_, Zhang,1982, p. 64, pl. 5, figs. 1–15.

*Orbitolina* (*Mesorbitolina*) _cotyliformis_, Zhang, 1982, p. 115, pl. 5, fig. 4.

*Orbitolina* (*Orbitolina*) _sp._, 1986, p. 116, pl. 7, fig. 11.

*Orbitolina* (*Mesorbitolina*) _texana_ (Roemer), Zhang, 1986, p. 111, pl. 4, figs. 7-17.

**Discussion:** This species is characterised by an almost square embryonic apparatus, with clear deutoconch and sub-embryonic zone, each divided by radial partitions. Zhang (1982, 1986) described a number of new species similar to *M. texana* (see list of synonyms) from the Aptian of Takena Formation in Xizang, China.

**Distribution:** This species is found in this study in the Aptian to Albian (PZ Aptian 4a–Albian 1, TLKc–TLK1d) of Azhang, Guolong sections and in the Coqen basin.
Mesorbitolina subconcava (Leymerie, 1878)

Figs. 10.6, 11.5

Orbitolina subconcava Leymerie, 1878, pl. E, fig. 7.

Orbitolina (Orbitolina) bangoinica Zhang, 1982, p.73, pl. 12, figs. 1–6.

Orbitolina (Mesorbitolina) aspera Zhang, 1986, p. 112, pl. 5, figs. 7–9.

Orbitolina (Mesorbitolina) imparilis Zhang, 1986, pl. 6, figs. 5–10.

Orbitolina (Mesorbitolina) langshanensis Zhang, 1986, p. 113, pl. 8, figs. 1–5.

Orbitolina (Mesorbitolina) xainzaensis Zhang, 1986, p. 114, Pl. 7, figs. 6–7.

Discussion: M. subconcava is characterised by an oval proloculus surrounded by a well divided deuteroconch and subembryonic zone. Zhang (1982, 1986) described similar species to M. subconcava from the Lower Cretaceous of the Lhasa Block, Tibet (see above synonyms).

Distribution: This species is found in this study in the Aptian and Albian (latest Aptian 4a–Albian 4, upper part of TLK1c–TLK1g) of Azhang, Guolong sections and in the Coqen basin.

Mesorbitolina aperta (Erman, 1854)

Figs. 11.1–11.4, 11.6–11.7

Orbitolites apertus Erman, 1854, p. 603–60, pl. 23, figs. 1–3.

Orbitolina (Mesorbitolina) gigantea Zwang, 1986, p. 115, pl. 7, figs. 8–10.

Orbitolina (Orbitolina) toihica Zwang, 1986, p. 116, pl. 8, figs. 8–11.

Discussion: This species is characterised by a deuteroconch subdivided in the upper part by several partitions of different sizes, whereas the lower part exhibits an irregular
network of partitions. Zhang (1986) created two new species, *O. (M.) gigantea* and *O. (O.) toihaica*, that are similar to *M. aperta* from the lower Cretaceous of the Lhasa Block (Tibet).

*Distribution:* This species is found in this study in the Albian to Cenomanian (Albian 3–Cenomanian 1, upper part of TLK1g–TLK1h) of Azhang, Guolong sections and in the Coqen basin.

**Genus:** *Praeorbitolina* Schroeder, 1964

**Type species:** *Praeorbitolina cormyi* Schroeder, 1964

*Praeorbitolina wienandi* Schroeder, 1964

Fig. 12.1

*Praeorbitolina wienandi* Schroeder, 1964, p. 412, text-fig. B.

*Orbitolina (Eorbitolina) robusta,* Zhang, 1982, p. 74, pl. 1, figs. 10–13.

*Discussion:* *Praeorbitolina wienandi* is distinguished in having an embryo followed by an initial spiral of only 2–3 cuneiform postembryonic chamber layers. It was described as *O. (E.) robusta* new species by Zhang, 1982 from the Aptian of取那Formation in Xizang, China.

*Distribution:* This species is found in this study in the Aptian (PZ Aptian 2–late TLK1a) in Jiarong, Laxue, Azhang and Guolong sections and in the Linzhou basin.

**PHYLOGENETIC EVOLUTION AND BIOZONATION**
In our study, sixteen species of orbitolinids forming four different lineages have been recognised (see Fig. 8). They belong to the *Palorbitolina lenticularis–Palorbitolinoides hedini* lineage (Cherchi & Schroeder, 2013); *Praeorbitolina cormyi–Mesorbitolina texana* lineage (Cherchi & Schroeder, 2013), which extends into the here newly identified *Mesorbitolina subconcava–Mesorbitolina birmanica–Mesorbitolina aperta* lineage; the *Conicorbitolina* lineage. *Orbitolinopsis* has been here registered for the first time from Tibet from the Late Aptian of Tibet.

Cherchi & Schroeder (2013) traced the evolution of *Praeorbitolina cormyi* to *Mesorbitolina aperta* without integrating *M. birmanica* in the lineage. *Mesorbitolina birmanica* was first insufficiently described in 1937 by Sahni, however, the description of the types was subsequently emended by Sahni & Sastri (1957). *Mesorbitolina birmanica* has been identified by many authors from Tibet, Iran, and India (see Schlagintweit & Wilmsen, 2014; Rao et al., 2015). It is characterised by a biconvex embryonic apparatus, which includes a plano-convex protoconch and a deuteroconch that is irregularly subdivided by occasional partitions. It is considered here as belonging to the ancestral stock of the *Mesorbitolina subconcava – aperta* group with a comparatively larger and more complex embryonic apparatus. The deuteroconch in *M. subconcava* is generally subdivided by short subdivision, which reach the lower part of the protoconch (Schroeder et al., 2010), while the deuteroconch of *M. aperta* is initially subdivided by several sets of alveoli, which become intense and irregular in the advanced forms in the Early Cenomanian. *Mesorbitolina birmanica* has been previously reported from Tibet by Zhang (1982, 1986, 1991), and ranges here from latest Aptian (Aptian 4b, 115.0 Ma) to Late Albian (Albian 4, 100.5Ma). On other hand, *M. subconcava* ranges from Late Aptian (latest Aptian 4a, 116.0Ma) to Late Albian (Albian 4, 100.5Ma), while *M. aperta* is Late Albian (Albian 3, 106.7Ma) to Early Cenomanian in age (Cenomanian 1, 98.8 Ma).
Orbitolinopsis and Paleodictyoconus are common in the upper Aptian assemblages. We refer to their species as Orbitolinopsis sp. A and Paleodictyoconus sp. A on the basis of limited material. In this lineage Orbitolinopsis sp. A occurs in the earliest Late Aptian (earliest Aptian 4). The test is relatively small, up to 1 mm in diameter, conical with a flat base. Its apex is twisted as in Urgonina, however the first coil is lost, leaving just an off-centered embryonic apparatus and the radial partitions anastomose centrally to form reticulate zone in transverse section. The chambers are rectangular to discoidal, lacking tiers of peripheral chamberlets. The off-centred proloculus is globular, slightly larger than the oval deuteroconch. Paleodictyoconus sp. A occurs in the latest Late Aptian (latest Aptian 4), and is characterised by a narrow marginal zone that is subdivided by radial beams, with those of adjacent rows alternating in position. The off-centered proloculus is still globular, but is followed directly by a small deuteroconch and a small spire of peri-embryonic chambers. This species differs from the Early Cretaceous Paleodictyoconus arabicus (Henson) in having fewer concentrated partitions.

Conicorbitolina first appears in the Late Albian (Albian 4, 102.2 Ma) as C. cf. cuvillieri, a markedly conical species with a spherical embryonic apparatus, partially obscured in many sections. However, the spherical protoconch and the cup-shaped deuteroconch clearly defines this species as Conicorbitolina. The relatively small size of the embryonic apparatus (~0.2 mm in diameter), and the subembryonic area divided by many radial partitions are comparable with typical C. cuvillieri. Conicorbitolina develops a much larger embryo (0.8–0.9 mm) in the Cenomanian, and develops into a less conical form, described here as Conicorbitolina sp. A. Due to limited material, however, both forms are indeterminable at a specific level.

The co-occurrence of LBF with PF at some levels of the mid-Cretaceous is vital for the correlation and refining the biostratigraphy of some of the long-ranging LBF. All the LBF
were identified and the main species are plotted in Fig. 9, in relation to the proposed foraminiferal biozonations. In our definitions of stratigraphic ranges, we primarily use the PF zonal scheme of BouDagher-Fadel (2013), which is tied to the time scale of Gradstein et al. (2012). The integration of the material described in this study has enabled us to define eight mid-Cretaceous biozones that extend the previous Tibetan biozones for the Late Cretaceous and Early Paleocene described by BouDagher-Fadel et al. (2015), thus:

**TLK1a** (Jiarong section 13LZ18–13 and Laxue section 14LZ18–12 in the Linzhou basin, PZ Aptian 1–2, 126.3–119.5 Ma). This biozone is characterised by the first appearance of *Pseudochoffatella cf. cuvillieri* (Fig. 9.9). It includes primitive orbitolinids, such as *Palorbitolina lenticularis* (Fig. 9.1) and planipiral forms with alveolar walls, such as *Pseudocyclammina* sp. A (Fig. 9.8). *Praeorbitolina wienandi* (Fig. 9.2a), *Praeorbitolina cormyi* (Figs. 9.2b, 9.3–9.7) and *Mesorbitolina lotzei* made their first appearances in the upper part of this biozone.

**TLK1b** (Azhang section in the Coqen basin: 12LS01–12LS05, PZ Aptian 3, 119.5–116.5 Ma). This biozone is characterized by the first appearance of *Mesorbitolina parva* (Figs. 10.1, 10.3). *Palorbitolina lenticularis, Palorbitolinoides orbiculata* with rare ataxophragmids, such as *Vercorsella camposaurii, V. arenata, Sabaudia capitata, Opertum* sp., triserial to biserial chrysalinids such as *Chrysalidina* sp., *Praechrysalidina* sp., *Dukhania* sp., rare nezzazatids, such as *Nezzazatinella* sp., small miliolids, *Textularia* spp., agglutinated foraminifera with alveoles such as, *Everticyclammina* sp., *Pseudocyclammina* sp. A and rare dasyclads are also present.

**TLK1c** (Azhang section 12LS06–17 and Guolong section 13GL195–141 in the Coqen basin, PZ Aptian 4, 116.5–113.0 Ma; Sangzugang section 10SZG–B, C,04,10 in the Xigaze basin). This biozone is characterised by the first appearance of *Mesorbitolina texana* (Figs. 10.2, 10.4–10.5). *M. parva* (Figs. 10.1, 10.3), *M. birmanica* (Fig. 9.10),
Palorbitolinoides orbiculata, Sabaudia capitata, Vercorsella camposaurii, V. arenata, (Fig. 11.11) Orbitolinopsis sp. A (Figs. 12. 4a–12.6), Paleodictyoconus sp. A. (Figs. 12.3–12.4b) are common. Palorbitolina lenticularis become extinct within the early part of this biozone where assemblages are dominated by robust, shallow, clear-water, convex to concave forms of orbitolinids. In the upper part of this biozone, orbitolininds are replaced gradually by small agglutinated forms, such Everticyclammina sp. A (Fig. 12.9), Pseudocyclammina spp., Buccicrenata spp., Chrysalidina sp., Vercorsella arenata, Mayncina sp, Daxia minima, Sabaudia minuta, S. capitata. Rare Mesorbitolina texana remain constantly present with rare species of M. subconcava appearing for the first time. Codiacean, dasyclad algae and gastropod spp. are common. Everticyclammina sp. A (Fig. 12.9), planispiral with a very short initial coil, followed by an elongate uniserial part with a single areal aperture and an alveolar wall with the septa remaining solid, dominate the assemblages. This species is similar to the advanced E. greigi (see BouDagher-Fadel, 2008) in which the lower parts of the adult septa are oblique, then tangential to the spiral suture, and thicken and coalesce to form imperforate basal layers to the chambers.

• **TLK1d** (Azhang section 12LS18–56, Guolong section 13GL86–59 and 13GL196 in the Coqen basin, PZ Albian 1, 113.0–109.8 Ma). This biozone is characterised by the first appearance of Cuneolina pavonia (Fig. 11.8) and Nezzazata sp. Assemblages include Mesorbitolina texana, M. subconcava, M. birmanica, Palorbitolinoides orbiculata (Fig. 10.8), Buccicrenata sp., Stomatostoecha plummerae, Nezzazata sp., Nezzazatinella sp., Cuneolina parva, Sabaudia minuta, Vercorsella scarsellai, Pseudocyclammina sp., and Ovalveolina sp. Small miliolids and dasyclad algae are common.

• **TLK1e** (Azhang section 12LS55–63 and Guolong section 13GL57–51 in the Coqen basin, PZ Albian 2, 109.8–106.7 Ma). This biozone is characterised by the first appearance of Palorbitolinoides hedini (Fig. 10.9). Assemblages include Mesorbitolina
subconcava (Figs. 10.6, 11.5), M. birmanica, Palorbitolinoides orbiculata, Vercorsella scarsellai, Buccicrenata sp., Sabaudia minuta, Cuneolina parva, C. pavonia and small miliolids. Planktonic foraminifera, such as Favusella washitensis (Fig. 12.2), and dasyclad algae are also rare.

- **TLK1f** (Azhang section 12LS64–86 and Guolong section 13GL50–41 in the Coqen basin, PZ Albian 3, 106.7–102.2 Ma). This biozone is characterised by the first appearance of Mesorbitolina aperta (Figs. 11.1–11.4, 11.6–11.7). Assemblages are dominated by Mesorbitolina subconcava, M. birmanica, Vercorsella scarsellai, Buccicrenata sp., Cuneolina pavonia and Textularia spp.

- **TLK1g** (Azhang section 12LS87–89, Guolong section 13GL40–34 and the Xiagezi section 13DW04–7 in the Coqen basin, PZ Albian 4, 102.2–100.5 Ma). This biozone is characterized by the first appearance of Pseudochoffatella cuvillieri (Figs. 12.7–12.8). Assemblages include Mesorbitolina subconcava, M. aperta, M. birmanica, Cuneolina pavonia, Vercorsella scarsellai, Sabaudia minuta, Buccicrenata sp., Hemicyclammina sp., Pseudocyclammina cf. rugosa, Pseudocyclammina sp. B, Conicorbitolina cf. cuvillieri, Stomatostoecha plummerae, Nezzazata sp., Nezzazatinella picardi, and rare planktonic foraminifera Ascoliella quadrata, Favusella sp. are also present. We have also found in this assemblage a primitive form, Praeorbitolina cf. wienandsi (Fig. 12.1), thus extending the range of Praeorbitolina to the top of the Albian in this area.

- **TLK1h** (Azhang section 12LS90–120, Guolong section 13GL34–18, Xiagezi section 13DW07–11 in the Coqen basin, PZ Cenomanian 1, 100.5–98.8 Ma). This biozone is characterized by the first appearance of Conicorbitolina sp. A (Fig. 10.7) and Nezzazata conica (Fig. 12.11). Assemblages include Mesorbitolina aperta (Figs. 11.1–11.4, 11.6–11.7), Conicorbitolina cf. cuvillieri, Sabaudia minuta, Cuneolina cf. cylindrica, Pseudocyclammina
sp. B, Cuneolina parva, C. pavonia (Fig. 11.8–11.10), Daxia cenomana, Nezzazatinella picardi, Buccicrenata sp., Pseudocyclammina sp. B and Pseudedomia sp.

The almost continuous sedimentary sequences also allowed the recognition of four phylogenetic lineages for the Tibetan orbitolinids, namely:

- the *Praeorbitolina – Mesorbitolina* lineage of Aptian – Early Cenomanian age, previously defined by Cherchi & Schroeder (2013) is confirmed. However, we also prove the range of the Early Aptian *Praeorbitolina* of this lineage extends to the top of the Albian in the Tibetan platform (Fig. 12.1, 13), and we integrate *Mesorbitolina birmanica*, which exhibit a rather large and complex biconvex embryonic apparatus with a plano-convex protoconch, within the Early Aptian to Early Cenomanian *Mesorbitolina* lineage (*M. lotzei–M. aperta*);

- the *Palorbitolina - Palorbitolinoides* lineage of Aptian – Albian age, previously defined by Cherchi & Schroeder (2013) is also confirmed. However, we extend the range of *Palorbitolina lenticularis* into the latest Late Aptian. In addition, we prove that the age of *Palorbitolinoides orbiculata* extends into the Early Albian (see Fig. 13 for age range of key species).

Our data show that the Takena limestones in the Linzhou basin have an Aptian 1, TLK1a, age while the Sangzugang limestones in the Xigaze basin correspond to the age of Aptian 4, TLK1c. The Langshan limestones have a relatively longer duration spanning from Aptian 3, TLK1b to Cenomanian 1, TLK1h. The age and LBF biozone correlation of mid-Cretaceous limestones in the three sedimentary basins of the Lhasa terrane are shown in Fig. 14.

PALEOENVIRONMENT OF THE MID-CRETACEOUS CARBONATE FACIES
The mid-Cretaceous was a globally warm period, characterised by an increase in the number of agglutinated foraminiferal forms having large alveoles, such as *Pseudocyclammina*, or forms with internal radial partitions, such as the orbitolinids. This may have been as a consequence of adaptation to the extreme climatic and oceanic conditions during this interval (BouDagher-Fadel, 2008), linked to an inferred dramatic increase of carbon dioxide in the atmosphere, which may have been triggered by enhanced global volcanism (e.g., the Ontong Java flood events), and that led to an increase in temperature and oceanic anoxia (e.g., Kerr, 2006). The high CO$_2$ levels during this greenhouse period also would have led to increased oceanic acidity (Naafs et al., 2016), which would have favoured the development and ecological domination of agglutinated LBF forms, such as the orbitolinids, over those forms with biogenetically precipitated calcitic tests that dominated before and after this period.

As seen above, the mid-Cretaceous shallow marine limestones, which today occur in the Tibetan Plateau, have fossil assemblages that are dominated by the agglutinated orbitolinids, although *Pseudocyclammina* and *Dictyoconus* are also present. These agglutinated LBF thrived in many shallow carbonate environments (Arnaud Vanneau, 1980). The conical tests of the orbitolinids were strengthened by subdividing it into many small chamberlets, which likely housed within their walls symbiotic algae (see BouDagher-Fadel, 2008). By studying the size and shape of their test, Masse (1976) deduced that they had a free, epifaunal mode of life. They lived by lying on the sea-floor substrate, on the flat base of their conical test. Using associated algae, Banner & Simmons (1994) noted that *Palorbitolina lenticularis* was most common in sediments thought to be deposited at depths of 10–50 m. Orbitolinid-rich beds, with large, flat, orbitolinids seem to be characteristic of transgressive deposits, while more conical forms thrived in the shallowest water (Vilas et al., 1995; Simmons et al., 2000). This relationship of shape to palaeobathymetry has been observed in
different studies on living larger foraminifera for example, Reiss & Hottinger (1984) observed a flattening of *Operculina* tests with increasing water depth.

During this time, adaptive radiations in the shape of their tests and environmental control of growth-forms make LBF reliable paleoenvironmental indicators (see Simmons et al., 2010). Sedentary, attached LBF grew to accommodate the shape of the vegetable substrate to which they adhered (BouDagher-Fadel & Wilson, 2000). Those found attached on sediments in deeper waters tend to be flat and discoidal in shape (see BouDagher-Fadel, 2008). However, LBF are also very sensitive to light levels (BouDagher-Fadel, 2008), and water clarity is an important factor in their distribution and the way they grow. Being unicellular, LBF exhibit relatively rapid adaptation to environmental conditions through evolutionary modifications of their shape and structure. For example, shallow-water settings with high clay content have similiary populations of larger orbitolinids as those of the deeper water environments (Pittet et al., 2002). It is therefore, essential to analyse not only the shape of the orbitolinids, but all associated foraminifera to deduce their paleoenvironment. On this basis therefore, we can combine the analysis of the shape of the orbitolinids with that of the associated microfaunas and microfloras to infer the palaeoenvironmental history of the margin of the East Tethyan ocean during the mid-Cretaceous as follows (see Fig.15):

- A regressive phase of shallow reefal environment where small primitive orbitolinids, such as *Praeorbitolina* spp., dominate (TLK1a).
- A transgressive phase (TLK1b) or reefal to forereefal environment with assemblages dominated by large flat shaped orbitolinids (flattest around the maximum flooding surface).
- A reefal environment (TLK1c) shallowing abruptly to a backreef setting where orbitolinids are replaced by *Everticyclammina* spp. and small conical ataxophragmids (e.g.
Vercorsella arenata). These two phases of sea-level change were identified by Miller et al. (2011) (see Fig. 7).

- A transgressive phase (TLK1d) with the flat forms of Mesorbitolina texana dominating the assemblages. Many of the specimens of M. texana in the Guolong section were well sorted in size and direction by wave actions, reflecting their deposition in a high energy forereef environment (see Fig. 15).

- A regressive phase (TLK1e) where assemblages are dominated by small, broadly conical forms of orbitolinids (e.g., Palorbitolinoides hedini (Fig. 10.9). Planktonic foraminifera are present, but rare (e.g. Favusella washitensis, Fig. 12.2) indicating a low energy open marine reefal environment.

- A regressive phase (TLK1f) where assemblages are dominated by broadly conical (e.g., Mesorbitolina subconcava, Figs. 10.6, 11.5) to small convex orbitolinids (e.g., Mesorbitolina aperta, Figs. 11.1–11.4, 11.6–11.7) with abundant fragments of rhodophyte and dasyclad algae indicating a shallow reefal environment.

- A transgressive phase (TLK1g) of a reefal to forereef environment, reflecting the reported (Miller et al., 2011) rapid sea-level rise of over 50 m (see Fig. 7). Assemblages are dominated by broadly convex and flat orbitolinids (see Fig. 15). Planktonic foraminifera and forms with coarsely agglutinated epidermis, such as Pseudochoffatella cuvillieri (Figs. 12.7–12.8) are frequent.

- A regressive phase (TLK1h) where foraminiferal assemblages are dominated by conical, relatively small orbitolinids, but with complicated embryonic apparati (e.g. Mesorbitolina aperta, (see Figs. 11.1–11.4, 11.6–11.7)), and small ataxophragmids, indicating the re-establishment of shallow reefal conditions following the reported (Miller et al., 2011) 50 m sea regression in the Early Cenomanian (see Fig. 7).
We found that the mid-Cretaceous carbonate successions in the Tibetan Himalayas evolved through eight depositional stages (see Fig. 15), which correlate well with the global sea level curve for the period (Miller et al., 2011; see Fig. 7), and from which we created eight biozones (TLK1a–h). The occasional presence of PF with orbitolinids (e.g., Fig. 12.2) provided the opportunity to define the biostratigraphic framework of the LBF in the studied sections. The biozones created in this study for the mid-Cretaceous of the Tibetan platform enables the correlation between the Langshan, Sangzugang and Takena Formations in the Lhasa terrane to be made.

A comparison between the mid-Cretaceous LBF associations of the Tibetan carbonate platforms with those of the southern Neo-Tethys margin and of southwest Europe show that the LBF are comparable with those developed over large parts of the Tethyan realm. The Tibetan orbitolinids seem to have only very few latest Aptian–Albian species (*Palorbitolina lenticularis, Mesorbitolina texana, M. parva*) in common with those of North America, however, Albian and Early Cenomanian lineages are comparable with those of Europe and the eastern Arabian Plate (see Schroeder, 2010). We further confirmed the *Praeorbitolina cormyi–Mesorbitolina texana* and the *Palorbitolina lenticularis–Palorbitolinoides hedini* lineages of Cherchi & Schroeder (2013), but also integrated a new *Mesorbitolina birmanica–Mesorbitolina aperta* lineage. Finally, we were also able to extend the range of the Early Aptian *Praeorbitolina* (e.g. *Praeorbitolina* cf. *wienandsi*, Fig. 12.1) to the top of the Albian, and present a revised range chart of the Tibetan forms in Fig. 13.

CONCLUSION
The foraminiferal bearing facies, used here as biostratigraphic and paleoenvironmental indicators, enabled us to define eight new biozones (TLK1 a–h), which complement the Late Cretaceous and Neogene biozones for this region previously described by BouDagher-Fadel et al. (2015). The biozonations erected here are based on the stratigraphic first occurrences of index foraminifera. The limestones are rich in LBF, the most significant of which are orbitolinids as they have long been recognised as useful biostratigraphic markers in mid-Cretaceous Tethyan carbonate platforms (Henson, 1948; Douglass, 1960; Schroeder, 1962; 1975; Hofker, 1963; Neumann, 1967; Arnaud Vanneau, 1975, 1980; Cherchi & Schroeder, 1980, 2013; Marcoux et al., 1987; Görög & Arnaud Vanneau, 1996). Occasionally the deeper water LBF assemblages co-occur with, or are interspersed with PF assemblages. The well-established PF biostratigraphic ranges (see BouDagher-Fadel, 2013, 2015) have enabled the confirmation and delineation of the biostratigraphic ranges of these co-existing LBF.

In addition to enabling the development and refinement of the eastern Tethyan carbonate biostratigraphy, the assemblages studied enabled the details of the paleoenvironment of the area to be inferred. The paleoenvironment is interpreted from the changes in the foraminiferal facies throughout the sedimentary succession. In the backreef carbonate facies, ataxophragmiids and everticyclamminids dominate the foraminiferal assemblages of small miliolids and textularids. However, in the reefal to outer neritic environments, orbitolinid facies dominate. The inferred paleoenvironmental development of the region correlates very well with the global sea-level variation deduced by Miller et al. (2011)

ACKNOWLEDGMENTS
We thank Zhong Han and Wei Zhang for their assistance in sampling the field. This study was financially supported by the Most 973 Project (2012CB822001) and the NSFC Project (41472081). We would also like to thank Mike Simmons for discussion on some species of *Orbitolina*.
