Abstract

Understanding how active dendrites are exploited for behaviorally relevant computations is a fundamental challenge in neuroscience. Grid cells in medial entorhinal cortex are an attractive model system for addressing this question, as the computation they perform is clear: they convert synaptic inputs into spatially modulated, periodic firing. Whether active dendrites contribute to the generation of the dual temporal and rate codes characteristic of grid cell output is unknown. We show that dendrites of medial entorhinal cortex neurons are highly excitable and exhibit a supralinear input–output function in vitro, while in vivo recordings reveal membrane potential signatures consistent with recruitment of active dendritic conductances. By incorporating these nonlinear dynamics into grid cell models, we show that they can sharpen the precision of the temporal code and enhance the robustness of the rate code, thereby supporting a stable, accurate representation of space under varying environmental conditions. Our results suggest that active dendrites may therefore constitute a key cellular mechanism for ensuring reliable spatial navigation.

Introduction

Active, voltage-dependent conductances in neuronal dendrites transform the relationship between synaptic input and neuronal output. The resulting enrichment of the integration capabilities of single neurons has long been suggested as being exploited for computations relevant to behavior. However, the details of how specific active dendritic mechanisms are involved in behavioral computations have proved to be elusive. Recent work has provided evidence that the active properties of dendrites are engaged in somatosensory and visual cortical neurons during sensory processing. Moreover, dendritic nonlinearities also appear to be activated during behavioral tasks involving spatial navigation. While these studies have provided important correlative evidence that dendritic mechanisms are engaged under various circumstances, they do not provide a quantitative link for explaining how specific biophysical mechanisms can contribute to behavioral computations.

Grid cells in medial entorhinal cortex (MEC) represent a particularly attractive model system for linking cellular and circuit mechanisms to a behaviorally relevant computation. Grid cells exhibit a striking spatial code, with firing fields that span the environment of a navigating animal in a periodic hexagonal pattern, and have thus been proposed as representing a neural mechanism for path integration. Moreover, there exist several well-developed single-cell and network models of grid cell generation, providing a rigorous quantitative framework for understanding how particular biophysical mechanisms relate to the computation of spatial location. Layer 2 of MEC (MECII) contains the highest proportion of grid cells, and stellate cells, which form most of the MECII principal cell population, are likely grid cell candidates. In stellate cells, the correlation between somatically recorded synaptic responses and the dorsoventral gradient in grid spacing has suggested that intrinsic voltage-gated conductances may be important for generating grid cell firing. However, very little is known about whether the dendrites of stellate cells are electrically excitable, and thus their contribution to grid cell firing is unclear.

Here we have combined in vitro two-photon glutamate uncaging and in vivo patch-clamp recording with modeling to assess the role of active dendrites in grid cell firing. We show that stellate cells have active dendrites that perform supralinear input–output transformations in vitro. We also identify electrophysiological signatures consistent with active dendritic integration in vivo, including membrane potential-dependent boosting of excitatory postsynaptic potentials (EPSPs) and plateau potentials. We place our results in the context of single-cell and network models of grid cell firing and use modeling to show that active dendrites can promote the robustness of the grid cell rate code while sharpening the precision of the temporal phase precession code. Thus, dendrites of principal cells in MECII are highly excitable, and these active dendritic properties can enhance the accuracy and stability of the spatial map represented by grid cell firing.

Results

Supralinear integration in dendrites of MECII principal neurons

To assess how grid cells integrate synaptic inputs in single dendritic branches, we performed two-photon glutamate uncaging on dendritic spines of principal neurons in MECII (Fig. 1a). Activation of individual spines in MECII stellate cells produced glutamate uncaging-evoked EPSPs comparable to physiological synaptic responses (Fig. 1b and Supplementary Fig. 1). Activating increasing numbers of spines along a single dendrite or on two nearby dendrites evoked responses that were larger than the arithmetic sum of the corresponding individual responses (64 ± 8% supralinearity for intervals of ≤1 ms; n = 34 dendritic branches; Fig. 1b,c and Supplementary Fig. 2). Since recent data suggest that some MECII pyramidal cells may also display grid cell firing, we also carried out experiments on MECII pyramidal cells and obtained similar results (Fig. 1d and Supplementary Fig. 3). The degree of supralinearity in stellate cells did not significantly scale with distance from the soma (Supplementary Fig. 4) but was reduced to 10 ± 9% (n = 6) when the intervals between spine activations were extended to 8 ms, demonstrating that it depends on millisecond timing of the inputs (Fig. 1d).
Signatures of active dendrites in stellate cell recordings in vivo

To determine whether active dendritic integration occurs in grid cells in vivo, we searched for the signatures of supralinear dendritic integration, as identified in our slice recordings, in patch-clamp recordings from MECII neurons of mice navigating in virtual reality 18 (Fig. 3). By examining the differentiated membrane potential traces (dV/dt), we identified large peaks that were below the voltage threshold for action potentials and that were preferentially clustered around the peak of theta membrane potential oscillations (Fig. 3a), at a similar theta phase as action potentials during grid
field crossings\textsuperscript{17, 18}. These dV/dt peaks in vivo were comparable in amplitude to dV/dt peaks of glutamate uncaging-evoked EPSPs exhibiting dendritic spikes in vitro (Fig. 2a and Supplementary Fig. 7). The in vivo dV/dt peaks were correlated with large depolarizations in V\textsubscript{m} with amplitudes of up to ~6 mV (Fig. 3b), consistent with them being EPSPs that were boosted by activation of voltage-dependent conductances.

Figure 3: Engagement of active dendritic conductances in MECII principal neurons in vivo.

To probe the mechanisms underlying these dV/dt signatures in more detail, we used our experimental results to constrain a detailed compartmental model of MECII stellate cells that captures their measured passive, active and synaptic properties (Supplementary Fig. 8). Simulating grid cell firing in a model incorporating dendritic Nav and NMDAR channels reproduced the experimentally observed dV/dt signatures, including the correlation of dV/dt peak amplitudes with V\textsubscript{m} (Fig. 3c). When dendritic Nav and NMDAR channels were removed from the model, these signatures were abolished (Fig. 3c). In our in vivo experimental data, the fastest-rising events occurred within the 90° phase-bin preceding the peak of theta membrane potential oscillations (MPOs; Fig. 3d,f). This phase-bin also contained a larger fraction of particularly fast events with maximal rates of rise resembling or exceeding the maximal rates of rise of fast dendritic spikes that we observed during our somatic in vitro recordings (Fig. 3f). These observations could also be faithfully reproduced by the model generating dendritic Na\textsuperscript{+} spikes in the presence of dendritic Nav channels but not in their absence (Fig. 3e,g).

To further quantify the contribution of nonlinear dendritic conductances to grid cell firing, we compared NMDAR activation and dendritic input currents in detailed compartmental models of stellate cells with active or passive dendrites (Supplementary Fig. 9). These simulations showed that during grid cell firing, with V\textsubscript{m} trajectories representative of our in vivo recordings, NMDARs were substantially recruited (Supplementary Fig. 9a) and dendritic input currents were nonlinearly amplified by active, voltage-dependent conductances (Supplementary Fig. 9b). Furthermore, the membrane potential distributions in putative dendritic recordings in vivo covered the nonlinear range of the NMDAR open-probability curve, implying that NMDARs were nonlinearly engaged in vivo (Supplementary Fig. 10). In summary, we observed clear signatures of active dendritic integration in the membrane potential of MECII principal neurons during navigational behavior in vivo.

Plateau potentials during putative dendritic in vivo stellate cell recordings

Next, we looked for direct evidence for activation of regenerative events in stellate cell dendrites in vivo. Excitable dendrites have been shown to produce long-lasting regenerative plateau potentials in several cell types, such as neocortical pyramidal cells\textsuperscript{30} and hippocampal CA1 pyramidal cells in vitro\textsuperscript{31} and in vivo\textsuperscript{31, 32}. We identified similar distinctive signatures of excitabile dendrites in putative dendritic patch-clamp recordings from MEC neurons in vivo (Fig. 4 and Supplementary Fig. 11). Dendritic recordings were identified by a range of characteristic features\textsuperscript{33}, such as slower action potential rise times and higher input resistances (Supplementary Fig. 12). Distinct, long-lasting plateau depolarizations could be observed following action potentials in both putative dendritic and somatic recordings (Fig. 4a,b). These plateau potentials occurred either spontaneously (Fig. 4a,b and Supplementary Fig. 13) or could be evoked by current injection in putative dendritic recordings (Fig. 4b). We found that both the frequency (the percentage of action potentials followed by plateau potentials) and the duration of evoked plateau potentials were well-correlated with parameters that are also indicative of dendritic recordings (Fig. 4c), suggesting that they could be preferentially evoked in distal dendrites. While the frequency of evoked plateau potentials per action potential was more than an order of magnitude higher in putative dendritic than in somatic recordings from stellate cells in vivo (14.7 ± 7.2% of action potentials followed by plateau potentials in putative dendrites, n = 6, versus 0.4 ± 0.4% in soma, n = 6; P < 0.05), spontaneous plateau occurred at comparable frequencies (1.9 ± 1.9% in putative dendrites, n = 6, versus 1.0 ± 1.0% in soma, n = 6; P = 0.22; Fig. 4d). Distinct plateau potentials could be evoked by current injections in 4 of 6 putative dendritic recordings but only in 1 of 6 putative somatic recordings (Fig. 4d). The results of these in vivo recordings indicate that plateau potentials could be
Slow supralinear integration promotes the robustness of the grid cell rate code

To provide a quantitative framework for understanding the contribution of active dendrites to generating the grid cell rate code, we used a rate-based continuous attractor network (CAN) model. Given that NMDAR activation underpins the various types of dendritic nonlinearities we discovered in grid cells, we implemented NMDARs as a slow, cooperative, supralinear integration mechanism in an existing CAN model of grid cell firing\(^3\), which allowed us to efficiently explore a large range of parameters and noise amplitudes (Fig. 5 and Supplementary Fig. 9). Adding NMDARs to the CAN model strongly enhanced grid cell firing in the presence of noise, measured by a range of metrics (Fig. 5a–h). Across a wide range of noise amplitudes, NMDARs reduced network drift and improved the network’s velocity response, resulting in higher gridness scores (Fig. 5i,j). Simulations in which we independently incorporated either supralinearity or a slow time-constant indicated that both mechanisms must act in concert to improve network performance (Supplementary Fig. 15). The robustness of these findings was confirmed by a spiking attractor network model consisting of integrate-and-fire neurons\(^34\), which also produces the best velocity response and the highest gridness scores when both mechanisms are engaged (Supplementary Fig. 16). Using actual animal trajectories to drive the rate-based model, we found that an NMDAR decay time constant of ~50 ms produced a minimum in velocity error and a maximum in gridness (Fig. 5k). This optimum is remarkably consistent with the NMDAR decay time constant we measured experimentally in stellate cells (46 ± 5 ms, \(n = 4\); Supplementary Fig. 17). Simulations using an artificially slowed animal trajectory (Fig. 5l) indicate that the optimum depends on a realistic animal velocity driving the network response. Thus, NMDAR kinetics optimized for animal velocity can produce marked robustness to noise in a CAN model of grid cell firing.
Although principal cells in MECII, which form a large part of the grid cell population, have been shown to exhibit a rich variety of nonlinear excitability in somatic recordings\textsuperscript{19, 25, 36}, there has been no direct information available about the contribution of dendritic excitability to the active

**Supralinear integration sharpens the precision of phase precession**

Finally, we investigated how the active dendritic conductances we revealed in stellate cells can contribute to the temporal phase precession code of grid cell firing\textsuperscript{25}. To determine the precise spike timing produced by oscillatory synaptic inputs, we drove our detailed compartmental MECII stellate cell model (Supplementary Fig. 8) by realistic synaptic input patterns derived from a hybrid CAN and oscillatory interference model based on in vivo recordings from grid cells\textsuperscript{18} (Fig. 6). While the model only produced weak phase precession in the absence of dendritic Nav channels (Fig. 6a–c), phase precession was strikingly precise when Nav channels were present in the dendrites (Fig. 6d–f). While the fast supralinearly provided by Nav channels was sufficient to sharpen phase precession even in the absence of distinct isolated regenerative events, the effect could further be enhanced if the model cell produced full-blasted fast dendritic spikes (data not shown). Further analysis showed that dendritic Nav channels can sharpen phase precession by shortening the suprathreshold part of membrane potential oscillations, enabling precisely timed spikes across the full extent of a grid firing field (Supplementary Fig. 18). In agreement with this analysis, adjusting the width of grid fields by increasing excitatory drive in the model without dendritic Nav channels failed to improve phase precession, as more mistimed spikes were produced in the center of the grid field (Supplementary Fig. 19). Thus, our combined modeling results show that active dendritic conductances can both stabilize the rate code and sharpen the temporal code of grid cell firing.

**Discussion**

We provide evidence that the dendrites of MECII principal cells are electrically excitable and exhibit a range of nonlinear dynamics. Our results reveal that the biophysical origins of dendritic nonlinearities in these cells—dendritic Nav and NMDAR channels—may underpin the two key aspects of the grid cell code. Dendritic Nav channels restrict the time window for action potential generation in an oscillatory interference model of phase precession, thereby improving the precision of the temporal code. NMDARs in turn improve the robustness of the grid attractor in a rate-based model of grid cell firing. Together, our results provide strong evidence that active dendrites make a critical contribution to a key behaviorally relevant computation in the mammalian brain. Our simulations also provide a general framework for understanding how active dendritic computations can stabilize attractor networks.

**Active dendrites in MECII principal cells**

Although principal cells in MECII, which form a large part of the grid cell population, have been shown to exhibit a rich variety of nonlinear excitability in somatic recordings\textsuperscript{19, 25, 36}, there has been no direct information available about the contribution of dendritic excitability to the active
properties of grid cells. Our in vitro experiments reveal that the dendrites of both types of principal neurons in MECII, stellate and pyramidal cells, exhibited nonlinear input–output functions and could trigger dendritic spikes mediated by both voltage-gated sodium channels and NMDA receptor channels. Moreover, they demonstrate that these nonlinearities could be further enhanced by in vivo-like membrane potential trajectories that underpin grid cell firing.

Our in vivo experiments strengthen and complement our in vitro results and provide multiple signatures of nonlinear dendritic integration in MEC neurons during spatial navigation. First, EPSPs were boosted at the peak of the MPOs when the neuron was depolarized, consistent with our in vitro experiments, as well as with predictions from a model with active dendrites (Fig. 3). Second, comparing a stellate cell model with nonlinear or linear dendritic conductances, we found that dendritic nonlinearities were robustly activated during simulations of grid cell firing (Supplementary Fig. 9).

Third, we observed nonlinear plateau potentials in putative dendritic whole-cell recordings from MECII neurons. We found that plateau potentials frequently occurred with dendritic but not somatic current injections, whereas spontaneous plateaus occurred with similar probability in somatic and dendritic recordings, indicating that the plateaus were of dendritic origin. Plateau potentials have been observed as a signature of dendritic excitability in other cell types, particularly in CA1 pyramidal cells, where dendritic plateau potentials can positively modulate existing or induce new place fields. Together, our modeling and experimental data suggest that the dendrites of grid cells are electrically highly excitable and that the resulting nonlinearities can be engaged in vivo during grid cell firing in mice performing a spatial navigation task.

How do active dendrites improve grid cell firing?

Our modeling results show that active dendrites can enhance both the rate and temporal code of grid cell firing. First, we show that incorporating a nonlinear NMDAR conductance, with characteristics matching those underpinning the nonlinearities in our in vitro experiments, in a CAN model of grid cell firing can reduce network drift and improve the network’s velocity response, resulting in improved gridness. Our simulations show that this enhancement of gridness arises from a synergistic interaction between two cardinal features of the nonlinear NMDAR conductance. First, NMDAR activation depends nonlinearly on the amplitude of the synaptic inputs that a neuron receives, increasing the gain of the neural transfer function preferentially in active neurons receiving strong spatial inputs. Second, the slow decay time constant of NMDARs allows active neurons to average signals over a longer time (see also refs. 38, 39, 40), reducing the contribution of noise and stabilizing the attractor. Notably, the stabilizing effect of NMDARs depends on the noise amplitude (Fig. 5i). Thus, acute blockade of NMDARs in grid cells should most strongly disrupt grid firing in novel environments, where spatial inputs are expected to be imprecise.

Our detailed compartmental model indicates that active dendrites also enhance phase precession, the signature of the temporal code of grid cell firing. Our simulations show that the mechanism underlying this effect operates by curtailing the suprathreshold part of the membrane potential trajectory during membrane potential oscillations. This ensures that spikes can occur only within a narrow time window, sharpening the precision of spike timing and thus the robustness of phase precession across the entire grid firing field. Notably, the effect of active dendrites on phase precession does not require the activation of full-blown dendritic spikes: even a model exhibiting subthreshold recruitment of nonlinearities demonstrates enhanced phase precession. Moreover, the model can reproduce the experimentally observed phase precession of both spikes and theta MPOs. The simplicity and robustness of this mechanism suggests that it may generalize to other phase precession models relying on coincidence of oscillations, such as those that have been proposed for CA1 pyramidal cells.

Our findings suggest that dendritic nonlinearities are key elements in the creation of a stable grid code and are therefore critical for navigation. This complements recent work proposing that dendritic nonlinear events may contribute to behaviorally relevant computations in single neurons. In hippocampal place cells, in vivo two-photon imaging has revealed dendritic Ca2+ transients that are correlated with their place field properties, and intracellular recordings from place cells suggest that dendritic nonlinearities may contribute to defining the spatial tuning of a neuron. Together with our in vivo results indicating that dendritic nonlinearities may also be engaged in MECII stellate cells during virtual navigation (Figs. 3 and 4), this suggests that active dendrites may provide a general mechanism for strengthening spatial representations at the single-cell level. Notably, the stabilizing role that we describe for active dendrites in a CAN may also generalize to other circuits that display attractor dynamics, both in the hippocampus and in other brain areas.

Why use active dendrites to enhance circuit computations?

Active dendrites offer several key advantages over alternative mechanisms—such as tuning somatic and axonal excitability, or excitation–inhibition balance—for improving the signal-to-noise ratio during grid cell firing. The nonlinear voltage-dependence of NMDAR activation exhibits exquisite sensitivity, being engaged already by a small number of synapses due to the high dendritic input impedance (Supplementary Fig. 20). At the same time, since dendritic synapses are electrotonically remote from the axonal site of action potential generation, nonlinear integration can proceed independently of somatic spiking. Moreover, by regulating the density of dendritic Nav channels and NMDARs, the threshold for supralinear integration can be widely adjusted over a large range of synaptic input frequencies to maximize the signal-to-noise ratio for grid cell firing. In contrast, changes in somatic and axonal excitability have only weak effects on the shape of the input–output transfer function of MECII principal neurons.

Furthermore, dendritic nonlinearities provide versatility, permitting a range of flexible transfer functions depending on the combination of dendritic branches that are activated (Supplementary Fig. 2). This allows grid cells to gate relevant inputs and suppress irrelevant inputs (similarly to what has been suggested for place cells). Finally, active dendrites may also provide a mechanism for shaping circuit wiring during development: early in the assembly of the entorhinal circuit, synaptic inputs that contact a nonlinear dendritic branch may be strengthened by engaging these nonlinearities and in turn define the grid properties of a neuron.

**Methods**

**Slice preparation.** Acute horizontal brain slices were prepared from 26–30-d-old C57BL/6 male and female mice. Animals were briefly anesthetized with isoflurane before decapitation. All procedures were approved by the local Animal Welfare and Ethical Review Board and performed under license from the UK...
Home Office in accordance with the Animals (Scientific Procedures) Act 1986. Slicing was performed in ice-cold sucrose solution, containing (in mM): NaCl 87, sucrose 75, glucose 25, NaHCO3 25, MgCl2 7, KCl 2.5, Na2HPO4 1.25 and CaCl2 0.5. For a period of 30 min immediately after slicing, slices were stored in preheated (32 °C) artificial cerebrospinal fluid (ACSF) with low Ca2+ and high Mg2+ concentrations, containing (in mM): NaCl 125, glucose 25, NaHCO3 26, MgCl2 7, KCl 2.5, Na2HPO4 1.25 and CaCl2 0.5. Slices were subsequently stored at room temperature (20–25 °C).

Experiments were performed in ACSF, containing (in mM): NaCl 125, glucose 25, NaHCO3 26, MgCl2 1, KCl 2.5, Na2HPO4 1.25 and CaCl2 2 at a temperature of 32–34 °C. After some recordings (Supplementary Fig. 3), the slices were fixed in 4% paraformaldehyde and immunohistochemical staining was performed using rabbit anti-calbindin (ab11426, Abcam) as the primary antibody and donkey F(ab')2 anti-rabbit IgG (Alexa Fluor 488, ab150069, Abcam) as the secondary antibody51. 52.

Electrophysiology and pharmacology. Somatic whole-cell patch-clamp recordings were obtained from stellate and pyramidal cells in layer 2 of medial entorhinal cortex. Stellate and pyramidal cells were identified by their somatodendritic morphology and their characteristic electrophysiological properties19, 25, 26, 36, 53, 54, 55, 56. Current-clamp recordings were acquired with a MultiClamp 700B amplifier at a sampling rate of 50 kHz using custom software written in Matlab. Patch pipettes of 5-MΩ resistance were filled with internal solution containing (in mM): KMeSO4 140, HEPES 10, KCl 7.4, MgCl2 0.3, EGTA 0.1, NaGTP 0.3, Na2ATP 3 and sodium phosphocreatine 1. Alexa Fluor 594 (50 µM) was added to this solution to visualize cell morphology. Series resistance of the recordings was usually less than 30 MΩ. In some recordings, 50 µM D-AP5 and 0.5 µM TTX were added to the regular ACSF solution to block NMDA receptors and voltage-gated sodium channels, respectively. All extracellular solutions were equilibrated with carbogen (95% O2/5% CO2) and had a pH of 7.3. Miniature EPSPs (mEPSPs; Supplementary Fig. 1) were measured in the presence of 0.5 µM TTX in the recording solution. The detection threshold for mEPSPs was defined as dV/dt ≥ 1 mV/ms.

To produce membrane potential ramps in vitro that mimicked membrane potential dynamics in vivo (Supplementary Fig. 6), we first applied the mean in vivo membrane potential waveform that we had previously recorded from stellate cells during firing field crossings 18 as a voltage clamp command in n = 5 stellate cells in vitro. The resulting clamp-current waveform was then averaged across recordings and injected as a current-clamp command to produce an in vitro-like voltage ramp. For voltage-clamp recordings (Supplementary Fig. 17), pipettes were filled with internal solution containing (in mM): CsMeSO4 135, HEPES 10, EGTA 0.3, NaGTP 0.3, Na2ATP 2 and MgATP 2. Series resistance was less than 15 MΩ. EPSCs were evoked by extracellular stimulation in layer I of MEC while holding MECCI stellate cells at a potential of +40 mV. NMDAR-mediated EPSCs were isolated by blocking GABA receptors with SR95531 (20 µM) and AMPA receptors with NBQX (10 µM).

Two-photon imaging and uncaging. Simultaneous two-photon imaging and two-photon glutamate uncaging was performed with two Ti:sapphire lasers tuned to 810 nm and 720–730 nm for imaging and uncaging, respectively. To visualize dendrites and dendritic spines, cells were loaded with a fluorescent dye (50 µM Alexa Fluor 594) added to the pipette solution. Healthy dendrites close to the surface of the slice were selected for uncaging. MNI-caged-L-glutamate (24 mM, Tocris) was dissolved in a solution containing (in mM): NaCl 125, glucose 25, KCl 2.5, HEPES 10, CaCl2 2 and MgCl2 1 and applied locally via a glass pipette (tip diameter ~10 µm). Multiple spines were selected in a randomized manner within a maximal distance of ~50 µm on a single dendritic branch. gluEPSPs were first evoked by stimulating each spine individually at 300 ms intervals, with a 10 ms pause between each trial. To estimate the expected linear summation of gluEPSPs, we first shifted individual membrane potential traces according to the corresponding experimental stimulation interval (0.6–8 ms for each trace) before computing the sum. Uncaging laser exposure time was 0.5 ms. The laser power was adjusted to produce gluEPSPs that were comparable to sEPSPs recorded in the same cell (Supplementary Fig. 1). Uncaging timing and location were controlled by custom software written in Matlab.

Experiments were terminated if photodamage to the dendrite was observed (for example, swelling of the dendrite) or depolarization of the membrane potential was detected. Recordings from neurons with photodamaged dendrites were excluded from analysis. Recordings were also excluded if the slice exhibited physical drift due to slice swelling or inconsistency of perfusion. This was detected either by imaging or by sudden large changes (usually decreases) in EPSP amplitude.

Data analysis. Data analysis was performed with custom code written in Python57. Nonlinearity, D, of each experiment was quantified by:

\[ D = \frac{\sum_{i=2}^{n} \left| I_i - \sum_{j=1}^{i-1} \frac{I_j}{i-1} \right|}{\sum_{i=1}^{n} \left| I_i - \sum_{j=1}^{i-1} \frac{I_j}{i-1} \right|} \]

where \( I_i \) is the amplitude of the measured EPSP, \( L \) is the amplitude of the EPSP constructed by linear summation of single synapse EPSPs, and \( n \) is the maximal number of synapses activated. Slow dendritic spikes were detected if the nonlinearity of the EPSP integral was 33% larger than the nonlinearity of the EPSP amplitude. A fast dendritic spike was defined as a step-like increase (>50%) in a plot of maximal dV/dt against the number of uncaging locations (Fig. 2 and Supplementary Fig. 3).

To examine whether signatures of active dendritic integration can be found in grid cells in vivo, we analyzed in vivo patch-clamp recordings from MECCII neurons 18. The full membrane potential (Vm) recording duration from n = 6 putative grid cells was used for this analysis. Peaks were identified in differentiated Vm traces (dV/dt) by detecting local maxima that exceeded 0.1 mV/ms within time windows of 200 µs. The analysis was restricted to subthreshold Vm by excluding parts of traces where dV/dt exceeded 5% of the maximal rate of rise of action potentials of each recording. Local Vm peaks corresponding to these dV/dt peaks were detected in high-pass-filtered Vm traces (fC = 10 Hz) within 5 ms following each dV/dt peak (Fig. 3b,c). dV/dt peaks were binned according to the phase of theta membrane potential oscillations (theta MPOs) during which they occurred. Theta MPOs were obtained by bandpass-filtering Vm between 5 and 10 Hz; 0° corresponds to the peak of theta MPOs. For each
theta MPO bin with a width of 45° (as indicated), mean and s.d. of all dV/dt peaks were computed for each recording (Fig. 3d–g). Moreover, for each theta MPO bin with a width of 90° (as indicated), dV/dt peaks that exceeded the mean of all dV/dt peaks within a given bin by 1.5 s.d. were computed for each recording (Fig. 3f,g). These particularly fast peaks are indicated by red symbols in Figure 3. According to these criteria, the lowest threshold for these fast peaks was typically a maximal rate of rise of ~0.4 mV/ms (Fig. 3d). Thus, these fast in vivo events were characterized by maximal rates of rise resembling or exceeding the maximal rates of rise of fast dendritic spikes recorded in vitro (typically ~0.4 mV/ms; Fig. 2a).

We analyzed plateau potentials across both somatic and putative dendritic in vivo patch-clamp recordings from MECII neurons. Plateau potentials were defined as sustained depolarizations following action potentials with a full-width-at-half-maximal amplitude exceeding 15 ms. These criteria were chosen to identify plateau potentials that closely resembled published examples (for example, Bittner et al.11). Action potentials were detected when dV/dt exceeded 30 mV/ms. We did not observe any obvious isolated plateau potentials without a preceding action potential in our data set. We analyzed a total of \( n = 58 \) recordings that produced trains of action potentials in response to depolarizing 1-s current injections. Recordings were categorized into putative dendritic and putative somatic recordings according to input resistance \( (R_{in}) \) and 20–80% rise time of action potentials \( (t_{20-80}) \) (putative somatic: \( t_{20-80} < 0.2 \) ms and \( R_{in} < 80 \) MΩ; putative dendritic: \( t_{20-80} > 0.3 \) ms and \( R_{in} > 120 \) MΩ). The frequency of plateau potentials did not depend on recording parameters such as resting membrane potential or seal resistance (Supplementary Fig. 11), indicating that recording quality did not affect their occurrence. To measure action potential kinetics (Fig. 4 and Supplementary Fig. 12), we used the first action potential that was evoked by the lowest suprathreshold sustained current injection.

Data are presented as mean ± s.e.m., unless stated otherwise. Error bars for dendritic spike proportions represent the s.d. of bootstrap analyses of the experimental data set (1,000 repeats). Statistical significance of continuous data was assessed using two-sided Mann-Whitney \( U \) tests and Wilcoxon signed-rank tests for unpaired and paired data, respectively. Statistical significance of dendritic spike proportions was assessed using Fisher's exact test. Analyses of variance (ANOVA) were performed when more than two groups were tested. Differences were considered statistically significant when \( P < 0.05 \). No correction for multiple comparisons was applied 58. No statistical methods were used to predetermine sample sizes, but our sample sizes are similar to those reported in previous publications11, 17, 18. Data collection and analysis were not performed blind to the conditions of the experiments.

### Compartmental modeling

Studying phase precession required us to model the precise timing of action potentials produced by oscillatory synaptic inputs. To achieve realistic predictions of membrane potential trajectories, we therefore decided to use a detailed compartmental model implemented in NEURON59 (Figs. 3 and 6 and Supplementary Figs. 8 and 20). We used a reconstructed morphology of a mouse MEC stellate cell25 and HCN channel gating kinetics based on experimental data from stellate cells60. Voltage-gated potassium (\( K_v \)) and sodium (\( Nav \)) channel kinetics were adopted from a CA1 pyramidal cell model61. Active conductance densities, axial resistivity \( (R) \), specific membrane resistance \( (R_m) \) and capacitance \( (C_m) \) were fitted to reproduce the experimentally determined mean \( f-I \) relationship, input resistance, sag ratio, sag time-constant, membrane time-constant, resting membrane potential and afterhyperpolarization amplitude using a genetic algorithm (NSGAII)62, 63, 64 (Supplementary Table 1).

Subthreshold synaptic input–output curves (Supplementary Fig. 8b) were produced by first finding all sites on the dendritic tree that were located 175 µm from the soma. We then performed simulations that closely followed our experimental protocol (Fig. 1): at each site, we distributed 20 synaptic conductances within 25 µm. We then activated individual synaptic conductance changes in isolation and computed the linear sums of the individual responses. Next, we stimulated an increasing number of synaptic conductance changes at 1-ms intervals and plotted the amplitudes of the measured responses against the amplitudes of the linear sums. This procedure was repeated for each site to yield a set of input–output curves. The analysis of simulated data was identical to that of experimental data.

To determine the effect of dendritic Nav channels on phase precession (Fig. 6 and Supplementary Fig. 19), we used a modeling and analysis strategy similar to one described previously18. In brief, we converted the synaptic inputs of rate-based neurons in a CAN model (see below) into discrete events driving synaptic conductance changes in our compartmental stellate cell model. Feedforward excitation was provided by six directional velocity-controlled oscillating (VCO) inputs that were only active when the current running direction matched the VCO's preferred direction ± 30° (ref. 65).

### Rate-based modeling (Fig. 5 and Supplementary Fig. 15)

Previous work has suggested that the mechanisms underlying the rate code of grid cell firing are best explained by a continuous attractor network (CAN) model17, 18, 68. We implemented a CAN model in a sheet of 128 × 128 neurons with periodic boundaries building on a previous implementation (courtesy of Y. Burak and I. Fiete15). This rate-based model allowed us to efficiently test the effect of a large range of parameters on network performance, which is essential for exploring the effects of a large range of noise amplitudes. The dynamics of rate-based neurons was defined by

\[
\begin{align*}
\dot{x}_i &= \left[ \frac{k}{y} \right]_{128} \text{ for } y_i > \text{th} \\
\dot{y}_i &= \left[ I_{\text{inh}}(y_i - 0.5) \right]_{128} + \sum_{j \neq i} w_{ij} \text{ for } y_i < \text{th} \\
\dot{s}_i &= \text{q} \cdot \sum_{j \neq i} \left( s_j \right)_{128} \\
\end{align*}
\]

where \( s_i \) represents the firing rate of neuron \( i \), \( V_i \) represents the membrane potential of neuron \( i \), \( \tau = 10 \) ms is the integration time constant of the neural response, \( k_{\text{NMDA}} = 0.4 \) (unless indicated otherwise) is the relative strength of NMDARs, \( p_{ij} \) is the fraction of open NMDARs in neuron \( i \) (equations (8) and (9)), \( I_{\text{inh}} \) is inhibitory recurrent input to neuron \( i \), \( B_i \) is excitatory feedforward input to neuron \( i \), \( W_{ij} \) is the synaptic weight from neuron \( j \) to neuron \( i \), and \( q \) is colored synaptic noise (equations (10)–(12)). By subtracting 0.5 from \( p_{ij} \), mean network firing rates were kept
approximately constant across simulations. For a threshold-linear implementation of the model without NMDARs, we set \( K_{\text{NMDA}} = 0 \). The gain of the neural transfer function, \( k \), was set to 0.88 (unless indicated otherwise), which minimized drift and velocity error for \( K_{\text{NMDA}} = 0 \). This strategy was chosen to ensure that reductions of drift and velocity error by NMDARs could not be explained by a simple linear gain change. The implementation of NMDARs as a multiplicative term is consistent with predictions of NMDAR recruitment in a compartmental model (Supplementary Fig. 9). \( B_i \) was defined by

\[
B_i = s_i (1 + a k_i v_i)
\]

where \( s_i \) is the unit vector pointing along neuron \( i \)'s preferred direction \( \varphi \) (one of \( W, N, S \) or \( E \)), \( v \) is the animal velocity vector in \( m \, s^{-1} \), and \( a \) was set to 0.0825. The recurrent weight matrix was purely inhibitory in our implementation:

\[
\begin{align*}
W_{\text{exc}}(i,j) &= \delta(i,j) - \delta(i-k,j-k) \\
W_{\text{inh}}(i,j) &= \delta(i-k,j-k)
\end{align*}
\]

where \( x \) is neuron \( i \)'s location in the neural sheet and ranges from \((-64, -64)\) to \((64, 64)\). In our implementation, we used \( k = 2 \), \( y = 1.02\beta \), \( \beta = 3\lambda^{-2} \) and \( \lambda = 13 \). \( \lambda_B = 10 \) and \( \lambda_W = 10 \) are scaling factors that were chosen to compensate for the ‘notau’ option in the original implementation. As in Burak and Fiete13, we computed the animal velocity vector \( v \) from an experimentally determined rat trajectory12.

It is currently unknown how spatially modulated excitatory and inhibitory inputs are distributed on the dendritic tree of grid cells. To implement a model that applies to a large range of potential synaptic input configurations, we therefore used a generalized approach in which we subject the sum of all synaptic inputs to a single function, which can take a nonlinear form.

The dynamics of NMDAR open probability \( p_i \) in neuron \( i \) was computed as follows:

\[
\tau_{\text{NMDA}} \frac{dp_i}{dt} + p_i = p_{\infty}(V_i) + \epsilon_P
\]

where the steady-state open probability, \( p_{\infty}(V) \), was assumed to be a sigmoid function of membrane potential \( V \) with center \( c_{\text{NMDA}} = 0.1 \) and slope factor \( m_{\text{NMDA}} = 0.2 \), yielding a neural transfer function that qualitatively matched the experimentally determined dendritic input–output curves. Unless indicated otherwise, \( m_{\text{NMDA}} = 0.2 \), \( \kappa_{\text{NMDA}} = 50 \) ms, in agreement with our experimental data (Supplementary Fig. 17).

Synaptic noise, \( \xi \), was implemented as an Ornstein-Uhlenbeck process using an exact update rule for an integration time step, \( h \)

\[
\begin{align*}
\xi_{\text{exc}}(t+\Delta t) &= \xi_{\text{exc}}(t) - \frac{\xi_{\text{exc}}(t)}{\tau_{\text{exc}}} + \sqrt{2D_{\text{exc}}} \xi(t)
\end{align*}
\]

where \( \xi_{\text{exc}} \) and \( \xi_{\text{inh}} \) are excitatory and inhibitory synaptic noise, respectively; \( \xi_{\text{exc},0} \) and \( \xi_{\text{inh},0} \) are average synaptic noise; \( \tau_{\text{exc}} \) and \( \tau_{\text{inh}} \) are synaptic time constants; \( G \) and \( G \) are random numbers drawn from a normal distribution with mean and standard deviation. \( A_{\text{exc}} \) and \( A_{\text{inh}} \) are amplitude coefficients given by

\[
\begin{align*}
A_{\text{exc}} &= \sqrt{2D_{\text{exc}}/\tau_{\text{exc}}} \\
A_{\text{inh}} &= \sqrt{2D_{\text{inh}}/\tau_{\text{inh}}}
\end{align*}
\]

where \( D_{\text{exc}} \) and \( D_{\text{inh}} \) are noise diffusion coefficients. Excitatory and inhibitory noise were assumed to be symmetric in our simulations, with \( \tau_{\text{exc}} = \tau_{\text{inh}} = 2 \) ms. Noise diffusion coefficients and average synaptic noise were set as high as possible without disrupting the periodic activity bumps in the CAN when the original simulation parameters from Burak and Fiete13 were used (\( \xi_{\text{exc},0} = \xi_{\text{inh},0} = 1.2 \), \( D_{\text{exc}} = D_{\text{inh}} = 0.04 \), yielding a ratio similar to \( \xi_0/D \), as in Destexhe et al. 67).

Integrate-and-fire neurons (Supplementary Fig. 16).

An implementation of a CAN model using integrate-and-fire neurons was adopted from Pastoll et al. 34. Topology and connectivity of the model were adopted from the original implementation: the network consisted of 68 × 56 excitatory and 34 × 50 inhibitory neurons interconnected in an ‘E-surround’ configuration34. Constant excitatory input currents to the excitatory neurons in the original model (\( I_{\text{ext},e,\text{const}} \) and \( I_{\text{ext},e,\theta} \)) were replaced by mixed AMPAR/NMDAR-type synapses driven by Poisson spike trains at 1 kHz. The dynamics of the synapses was defined by

\[
\begin{align*}
\frac{\text{d}g_{\text{AMPA}}}{\text{d}t} &= g_{\text{AMPA}} - g_{\text{AMPA}} = v \\
\frac{\text{d}g_{\text{NMDA}}}{\text{d}t} &= g_{\text{NMDA}} - g_{\text{NMDA}} = V - V_{\text{NMDA}} \text{and} \\
\end{align*}
\]

where \( g_{\text{AMPA}} \) and \( g_{\text{NMDA}} \) are the AMPAR and NMDAR conductances, \( V_{\text{NMDA}} = 0.5 \) defines NMDAR saturation, \( \tau_{\text{NMDA}} = 2 \) ms and
\[ x(t) = x(t)+w(V) \text{ and} \]
\[ (1) \]
\[ LAMP(t) = LAMP(t)+w \]
where \( w = 1 \) is the synaptic weight and \( p_{	ext{out}}(V) \) is the steady-state open probability of the NMDAR (equation (9)). Total synaptic conductance was computed as \( q_{	ext{AMPA}} + k_{	ext{NMDA}} / N_{	ext{MDA}} \). The maximal total conductance was set to 2.3 nS. A version of an AMPAR/NMDAR-type synapse without Mg\(^{2+}\) block was implemented by setting \( p_{	ext{out}}(V) = 1 \) in equation (18).

Spatial rate maps of model neurons were discretized into 1-cm \( \times \) 1-cm bins. No smoothing of the data was performed. To quantify spatial periodicity (‘gridness’), we first calculated the spatial autocorrelation for rate maps of each model neuron\(^2\). We then selected a centered ring-shaped region of interest from the autocorrelogram that included peaks closest to the center but excluded the central peak. We next rotated this ring in steps of 1° and at each step computed the correlation coefficient of the rotated with the original ring. We then determined maximal correlation values at 60° and 120° rotation (\( r_{\text{max},60} \) and \( r_{\text{max},120} \)) and minimal correlation values at 30°, 90° and 150° rotation (\( r_{\text{min},30} \), \( r_{\text{min},90} \), and \( r_{\text{min},150} \)). Gridness was then determined as \( \min(r_{\text{max},60}, r_{\text{max},120}) – \max(r_{\text{min},30}, r_{\text{min},90}, r_{\text{min},150}) \))\(^2\). Mean gridness values were computed for ten randomly selected model neurons.

Code and data availability.
Data analysis and simulation code are available on GitHub (https://github.com/neurodroid/SH2017; access available upon request). The data that support the findings of this study are available from the corresponding authors upon reasonable request.

A Supplementary Methods Checklist is available.
