Anatomy of a Joint: Comparing Self-Reported and Actual Dose of Cannabis and Tobacco in a Joint, and How These Are Influenced by Controlled Acute Administration

Chandni Hindocha,1,* Tom P. Freeman,1,2 and H. Valerie Curran1

Abstract

Introduction: Major gaps exist in the measurement of cannabis exposure. The accuracy of self-reported cannabis and tobacco dose per joint is poorly characterized and has never been investigated following acute cannabis/tobacco exposure. Using an innovative “Roll a Joint” paradigm, this study aims to (1) compare estimated and actual dose of cannabis and tobacco per joint at baseline and (2) examine the acute effects of cannabis and/or tobacco on estimated and actual dose.

Materials and Methods: We investigated this by using a randomized, double-blind, placebo-controlled cross-over 2 (active cannabis, placebo cannabis) × 2 (active tobacco, placebo tobacco) design in a laboratory setting. Participants were 24 recreational cousins of cannabis and tobacco. At baseline, they were asked to measure out the amount of cannabis and tobacco they would put in an average joint for themselves (dose per joint). Then, on each of four drug administration sessions, participants were again asked to do this for a joint they would want to smoke “right now.” Self-reported and actual amount was recorded (g).

Results: At baseline, the estimated amount of cannabis per joint (0.28 ± 0.23 g) was double the actual amount (0.14 ± 0.12 g) (p = 0.003, d = 0.723). No difference emerged between estimated (0.43 ± 0.25 g) and actual (0.35 ± 0.15 g) amount of tobacco per joint. Compared to placebo, active cannabis reduced the actual dose of both cannabis (p = 0.035) and tobacco (p < 0.001) they put in a joint. Participants accurately estimated this reduction for tobacco (p = 0.014), but not for cannabis (p = 0.680).

Conclusions: Self-reported dose per joint is accurate for tobacco but dramatically overestimates cannabis exposure and therefore should be viewed with caution. Cannabis administration reduced the amount of cannabis and tobacco added to joints, suggesting a reduction in dose during a smoking session. The “Roll A Joint” paradigm should be implemented for better accuracy in assessing dose per joint.

Keywords: cannabis; cannabis use metrics; coadministration; dose; quantity; self-report; tobacco

Introduction

Accurate cannabis use metrics are essential for assessing the effects of cannabis. In the field of alcohol research, the concept of a “standard unit” exists as a measure of consumption. However, there is no equivalent for cannabis and self-report measures of cannabis use are at best, only weakly correlated with objective measures.1 Such metrics are used mainly as a proxy for exposure to delta-9-tetrahydrocannabinol (THC), but come with many caveats. For example, people often share cannabis and the potency and quantity of the cannabis bought, especially where sales are not tolerated,
are often unknown. Moreover, the quantity of use is likely to be different across types of users, where recreational users are likely to use less cannabis, and therefore potentially more tobacco, than daily users. The absence of a standardized “cannabis unit” and methodological differences between studies hinder direct comparisons regarding the effects of cannabis.2–5 Moreover, the role of frequency of use is often overemphasized at the expense of quantity (e.g., amount of cannabis used per day, per joint, or joints per gram), which is also a predictor of problematic use.1,6–8

Another major issue is that worldwide, cannabis use is strongly associated with tobacco use.9,10 Particularly in Europe, cannabis is most commonly combined with tobacco into joints as the primary consumption method.11 In Europe, “joints” typically contain a mixture of cannabis and tobacco (and are interchangeably also referred to as “spliffs”). Hereafter, we refer to joints as a mixture of cannabis and tobacco; however, we acknowledge that in the United States, joints typically do not contain tobacco.12 Adding nicotine to cannabis may modify its dose by increasing the amount of THC released by almost half23 as well as affecting the subjective experience14,15 and cognitive effects of cannabis.15,16 Combining cannabis and tobacco in joints thus exposes users to tobacco, potentially leading to a vulnerability to both nicotine and cannabis dependence.17,18 Furthermore, cannabis users titrate (adjust) their dose based on the potency of cannabis therefore modifying total THC exposure.19,20 However, thus far, whether cannabis users also titrate their dose to tobacco content has not been investigated.

Two previous studies have investigated dose per joint using a cannabis substitute.21,22 The first did not measure tobacco21; the other used the same substitute to measure both cannabis and tobacco (which have different weights)22 and neither was conducted with cannabis smokers, where this issue is particularly pertinent.11 In one Dutch study, van der Pol et al.1 estimated dose per joint using actual cannabis, however, the amount of tobacco was not estimated. Moreover, there has been no research to date investigating how acute intoxication may influence self-reported and actual dose per joint. To maximize the ecological relevance of this laboratory study, our “Roll a Joint” procedure used a typical brand of rolling tobacco and a cannabis placebo, produced from active cannabis to contain less than 0.1% THC (but with the same terpene content, so it retains the look and smells of cannabis). We first aimed to compare peoples’ estimated and actual dose of cannabis and tobacco in joints. Second, we aimed to investigate how estimated and actual dose per joint is influenced by smoking cannabis and tobacco, both individually and combined in joints.

**Materials and Methods**

**Design and participants**

Participants took part in a baseline session and then four acute drug sessions. The acute effects of cannabis and tobacco, both alone and combined, were evaluated using a randomized, double-blind, placebo-controlled four-way crossover design. Previous data from this study have been published elsewhere on memory and psychotomimetic effects15 and reward processing.23 The four drug administration sessions (Table 1) were separated by at least 1-week washout (≥3 times elimination half-life of THC).24,25 Order of drug treatment was determined by a balanced Latin square.

Medically and psychiatrically healthy, nondependent but experienced, cannabis and tobacco cousins (i.e., “joint” smokers) were recruited from the community. Inclusion criteria were as follows: (i) 18–60 years; (ii) regular use (>once/month but <3 times/week) of cannabis mixed with tobacco in joints for the previous 6 months; (iii) self-reported ability to smoke one whole “standard” joint; (iv) normal or corrected to normal vision; (v) fluent English; (vi) self-reported abstinence from tobacco, cannabis, alcohol, and other drugs for at least 12 h before each test day; and (vii) alveolar carbon monoxide (CO) ≤6 ppm to confirm no recent smoking on each test day.12 Exclusion criteria were as follows: (i) ≥3 on the Cannabis Severity of Dependence

Scale; (ii) treatment-seeking for cannabis or tobacco use, or currently using nicotine replacement therapy or other cessation pharmacotherapy; (iii) smoking ≥10 cigarettes a day or scoring ≥4 on the Fagerström Test of Nicotine Dependence; (iv) first cigarette smoked within the first 3 hours after waking; (v) significant respiratory, physical, or clinically diagnosed learning impairments; (vi) clinically diagnosed schizophrenia or psychosis (or a first-degree family member with either), or substance use disorder; and (vii) illicit substance use other than cannabis more than once per week.

"Roll a joint" paradigm
This paradigm was designed as an ecological assessment of participant’s (a) typical dose per joint (at baseline) and (b) desired dose 1 hour after drug administration of both cannabis and tobacco. Ground placebo cannabis (which contains the precise terpene profile of the original strain, with all cannabinoids removed to <0.2% of dry weight; available from Bedrocan NL) and rolling tobacco (Amber Leaf, JTI) were used as substitutes. Two king-sized rolling papers (108 × 44 mm; Rizla Blue) were placed in front of the participant. At baseline, participants were asked to add the “amount of cannabis and tobacco they would typically put in a joint, if the cannabis and tobacco were of average strength and quality and they could smoke the whole joint by themselves.” One hour after drug administration on each drug occasion, participants measured out cannabis and tobacco in the same manner. They were asked to estimate how much the amount of cannabis and tobacco they want to smoke “right now.” They were then asked to estimate by sight (in g) the amount of cannabis/tobacco in each rolling paper. The weight of the cannabis and tobacco was recorded to the closest 0.01 g. Weighing took place under experimenter-blinded conditions and participants were not given any feedback on their accuracy.

Drug administration and procedure
The effects of (a) active cannabis and active tobacco (CAN + TOB), (b) active cannabis + placebo tobacco (CAN), (c) placebo cannabis + active tobacco (TOB), and (d) placebo cannabis + placebo tobacco (PLACEBO) were investigated (doses defined in Table 1; Fig. 1).

On each drug session, participants smoked a joint (Fig. 1). The inhalation procedure was fixed and timed by an experimenter to ensure consistency between participants and sessions. Participants were asked to inhale for 4 sec, hold their breath for 8 sec, and then exhale and break for 30 sec. This sequence was repeated until the joint was smoked up to a designated line (Fig. 1). Participants completed the “Roll a Joint” paradigm on the baseline session and at ~1 h after drug administration on each drug session. Visual Analogue Scale (VAS) ratings of ‘stoned’ (from not at all [0] to extremely [10]) were taken at −10, +10, +30, +40, and +70 min after drug administration. All participants provided written informed consent on each occasion. Ethical approval was given by the UCL Ethics Committee.

Statistical analysis
Bonferroni corrected paired sample t-tests were conducted between baseline “actual” and “estimated” dose to investigate participants’ accuracy in guessing dose. Linear mixed models, with a random intercept for “participant,” and two within subjects factors of cannabis (placebo; active) and tobacco (placebo; active) were implemented on both actual and estimated dose. The unstructured variance/covariance structure was selected. The
dependent variable of actual and estimated cannabis and tobacco was analyzed in separate models. VAS “stoned” scores were analyzed with a cannabis (placebo, active) × tobacco (placebo, active) × time (1 [pre-drug] vs. 2–5 [postdrug]) ANOVA, which used a Helmert contrast for time.15

Results
Demographics and drug history
Participants were 24 (50% female) recreational cannabis and tobacco smokers. Use of other drugs apart from cannabis, tobacco, and alcohol was minimal (Table 2). Twenty-nine percent (n = 7) of participants were regular tobacco smokers before they ever mixed it with cannabis, 46% (n = 11) had tried tobacco, but were not regular smokers, before mixing it with cannabis, and 25% (n = 6) had never tried tobacco before it was mixed with cannabis. They self-reported adding 53.52% ± 19.38% tobacco in their standard joint. They self-reported smoking skunk* 49.25% ± 30.74% of the times they smoked cannabis, followed by herbal cannabis† (34.7% ± 28.5%) and hash‡ (15.95% ± 14.10%), respectively.

Actual and estimated dose of cannabis and tobacco per joint
At baseline, there was a significant difference between the actual and estimated dose of cannabis participants would normally smoke (t23 = 3.36, p = 0.003, d = 0.723) where participants overestimated the dose twofold (Table 3). In contrast, for tobacco there was no difference between the actual dose and the estimated dose (t23 = 1.59, p = 0.125).

Across each drug condition the same effect was observed, suggesting participants were accurate in estimating the amount of tobacco (all t’s ≥0.93, all p’s ≥0.087) but overestimated by roughly 200% the amount of cannabis used (all t’s ≥2.62, all p’s ≤0.015).

With regard to the actual dose of cannabis that participants rolled after intoxication, there was a main effect of cannabis (F1,23 = 5.05, p = 0.035). Participants added less cannabis to their joints after smoking active cannabis (0.12 ± 0.03) compared to placebo cannabis (0.15 ± 0.02). There was no main effect of tobacco (placebo: 0.14 ± 0.03; active: 0.13 ± 0.02) or interaction with tobacco.

With regard to the actual dose of tobacco participants rolled after intoxication, there was a main effect of cannabis (F1,23 = 22.72, p < 0.001). Participants added less tobacco to their joints after active cannabis (0.19 ± 0.03) compared to placebo cannabis (0.30 ± 0.03). There was no main effect of tobacco (placebo: 0.27 ± 0.03; active: 0.23 ± 0.03) or interaction with tobacco.

There were no main effects or interactions for the estimated dose of cannabis (p’s > 0.05). However, there was a main effect of cannabis on the estimated dose of tobacco (F1,21 = 6.99, p = 0.014). After active cannabis (0.23 ± 0.04), participants correctly estimated they were using a smaller dose of tobacco than after placebo cannabis (0.36 ± 0.05). There was no main effect of tobacco (placebo: 0.31 ± 0.04; active: 0.28 ± 0.04) or interaction with tobacco.

Subjective effects
Stoned. There was a cannabis X time interaction (F1,23 = 61.17, p < 0.001, ηp2 = 0.74) that revealed a significant increase between cannabis and placebo from pre- to postdrug (Fig. 2). Predrug, there was no

![Table 2. Demographics and Drug History of Participants](http://online.liebertpub.com/doi/10.1089/can.2017.0024)
difference between active and placebo cannabis ($p=0.575$), however, active cannabis increased “stoned” ratings at all time points postdrug (all $p$’s $<0.001$). There was also main effects of cannabis ($F_{1,23} = 64.97$, $p < 0.001$, $\eta_p^2 = 0.74$) and time ($F_{1,23} = 151.30$, $p < 0.001$, $\eta_p^2 = 0.87$). There were no main effects or interactions with tobacco.

**Discussion**

This study examined estimated (self-report) and actual dose of cannabis and tobacco used in a joint. Recreational cannabis and tobacco users were assessed at baseline and after intoxication with cannabis and/or tobacco using a novel “Roll a Joint” paradigm. We used a matched placebo-cannabis and rolling tobacco to create an ecological method where their weights, smell, and appearance closely paralleled the active drugs.

Participants showed a twofold overestimation of the actual dose of cannabis they added to their joints, while accurately estimating the dose of tobacco. Importantly, this effect was replicated across all drug conditions. This suggests that overestimation of cannabis and accurate estimation of tobacco amounts are a reliable finding and impervious to acute intoxication with cannabis or tobacco. These data, alongside other studies, have found an equivalent downward titration either in the amount they rolled in joints\(^{20}\) or the amount they inhaled.\(^1\) For example, an Australian study that found participants overestimated the dose of cannabis to a similar degree, using a cannabis substitute,\(^{22}\) suggests that self-reported dose should be viewed with caution. One objective measure we would recommend is to implement this “Roll a Joint” paradigm. Given the near equivalent overestimation found in the cannabis

amount between this study and the previous study,\textsuperscript{22} we suggest that use of a substitute, when placebo cannabis is not available, is adequate as long as a weight adjustment is made. We highly recommend that if users mix cannabis and tobacco, those tobacco estimations are made with real tobacco and recorded, unlike in previous studies.\textsuperscript{1,21,22} We encourage investigators to utilize this methodology, however, precision in dose estimation remains a problem for other routes of administration as well, and therefore, further validation of dose estimation methods is required. Given the huge variation in popular cannabis routes of administration worldwide,\textsuperscript{11} it would be necessary to validate this method for other routes (e.g., pipes, bongs, and vaporizers). There is a stark difference between the methods by which people smoke cannabis in the United Kingdom, where this study was conducted and where smoking a joint with tobacco is the most prevalent route, and the United States, where smoking cannabis through a blunt or pipe is common.

After smoking active cannabis, participants reduced both the amount of cannabis and tobacco they put into their joints compared to placebo cannabis, suggesting this paradigm is sensitive to acute satiety. Participants were only able to estimate they were using less tobacco but not less cannabis, which may imply they were aware of their satiety to tobacco, but not cannabis. This may be a consequence of the lack of information about cannabis due to nontolerated sales, which means a greater level of uncertainty regarding potency and the total weight of cannabis bought (e.g., an eighth of an ounce may not actually be what the user receives) especially for recreational users.\textsuperscript{20} Tobacco, however, is sold in standardized weights and is therefore potentially easier to estimate. Moreover, it is important to note that participants were still experiencing acute drug effects at the time of testing. Tobacco and cannabis differ in their appearance and typical dose per joint, which may have influenced accuracy; however, these factors were not manipulated and therefore are unlikely to account for the present results.

In the current turbulent climate of cannabis policy globally, finding accurate and standardized cannabis use metrics is essential to monitor levels of cannabis and tobacco consumption.\textsuperscript{28} There has certainly been some movement toward defining a standard cannabis unit\textsuperscript{5} and certainly both frequency and quantity are important measurements.\textsuperscript{8} In Europe, the particular issue of smoking cannabis and tobacco is worrying and mostly disregarded.\textsuperscript{29} Understanding how much cannabis is in a joint will inform important drug policy discussions\textsuperscript{6} and improve research outcomes when estimating dose, especially as self-reported use is often the main outcome variable used to link cannabis consumption to health outcomes. It is essential that dose be taken into account alongside potency measures. Here we find many users were unaware of how much cannabis they put in their joints and are indeed \textit{doubling} this figure. To our knowledge, this is the first study to show that both actual and estimated tobacco in joints is sensitive to acute cannabis administration indicative of cross-substance satiety. To investigate this further, use of smoking topography would be an essential next step.\textsuperscript{19}

Strengths and limitations

This study used a double-blind, placebo-controlled, four-way, crossover design with recreational users to investigate actual and estimated dose of cannabis and tobacco in a joint. A previous study found that recreational users have a poorer understanding of cannabis potency than heavy users,\textsuperscript{20} suggesting these findings cannot be extended to, and thus require replication with, heavier (dependent) users. Indeed, the precision of all dose measurement is still limited unless the potency of the cannabis is a known factor. Future research should aim to investigate dose and potency together. This research was conducted with a moderate number of recreational cannabis and tobacco users, and this may limit its generalizability (e.g., to those who do not mix their cannabis with tobacco or to those who are dependent cannabis users). Furthermore, this study was not designed to investigate sex differences and therefore was not adequately powered to address this issue. At the same time, this “Roll a Joint” paradigm has advantages over purely self-report measures of dose. We recognize this study did not have biologically verified abstinence or absorption; however, this is unlikely to influence our results as the residual cognitive effects of cannabis rarely last beyond 24 h and should be minimal in infrequent users.\textsuperscript{30,31}

Conclusions

Self-reported dose per joint is an inaccurate cannabis use metric. Here we report that a simple, novel “Roll a Joint” paradigm can overcome these inaccuracies when collecting cannabis use metrics. Furthermore, compared to placebo cannabis, active cannabis reduces the amount of both cannabis and tobacco rolled in a joint indicative of downward titration.
