Abstract: An experimental study of the turbulent boundary layer, where waves propagate with a current, is presented in this paper. A wide range of test conditions have been covered, namely, flows over a rough bed and a smooth bed, combined flows in a large-scale oscillatory water tunnel and combined waves and currents in two flumes with different scales. Particle Image Velocimetry and Laser Doppler Velocimetry were employed to obtain the velocity field. Detailed analysis of eddy viscosity profiles calculated from the experiments leads to the conclusion that previous assumed profiles do not always accurately describe eddy viscosity distributions in a combined wave-current flow. The distributions of eddy viscosity are categorised into two types (two-layer or three-layer), based on the influence of wave motions superimposed. For those cases in the current-dominated regime, eddy viscosity profiles are similar to unidirectional turbulent currents. When combined flows are in the wave-dominated regime, three-layer eddy viscosity distributions are observed. For both types, a linear eddy viscosity profile is found to be present in the bottom 10 per cent of the turbulent boundary layer. Above this, the classic parabolic profile is observed, over the whole turbulent boundary layer for the first type and over 40 per cent of the turbulent boundary layer thickness for the second type. An empirical eddy viscosity distribution in the outer region is proposed for the second type. This newly developed eddy viscosity distribution provides guidance for numerical modellers in the field of wave-current interaction and for coastal engineers wishing to predict sediment transport.

Keywords: Wave-current interaction; Laboratory experiments; Oscillating water tunnel; Wave-current flume; Eddy viscosity.

1. Introduction

The topic of wave-current interaction (WCI) has received much attention in the past few decades due to its significant applications in the field of sediment transport and marine energy exploitation. For example, prediction of sediment transport rate and coastal morphology, design of harbour structures, pipelines and tidal turbines all require a sound understanding of wave-current interaction.

Theoretical studies of WCI have emerged in parallel with developments in turbulence modelling. In order to determine mean velocity profiles and bed shear stress under a combined flow where waves propagate with a turbulent current, the Navier-Stokes (N-S) and continuity equations have been solved analytically or numerically by four main approaches: i. Direct Numerical Simulations (DNS), which solve the N-S equations directly by numerical methods without any turbulence models, and therefore motions at all scales can be obtained from the

42 results; ii. Large Eddy Simulations (LES), which directly calculate large-scale turbulent eddies
43 and make approximations on small-scale ones using a subgrid-scale model (SGS model); iii.
44 Reynolds stress models (RSM) or RANS-based models, which directly compute components
45 of the Reynolds stress tensor through the Reynolds stress transport equations without relying
46 on an eddy viscosity concept; iv. Eddy viscosity models using the RANS-based approach,
47 including zero-equation models (algebraic models), one-equation models (Turbulent-Kinetic-
48 Energy models and the Spalart-Allmaras model), and two-equation models ($k - L$ models, $k -$
49 ε models and $k - \omega$ models).

50 Due to their massive computational costs, DNS and LES have not yet been applied to practical
51 engineering problems and are not included in the present work. The RSM approach also
52 requires substantial computational effort and is beyond the scope of this paper. Hence, the
53 present work is focused in particular on the eddy viscosity approximation, which is used widely
54 by coastal engineers.

55 The generalised concept of eddy viscosity, being a positive scalar coefficient, was put forward
56 by Boussinesq (1877) in analogy to molecular viscosity to relate the Reynolds stress tensor and
57 the mean strain rate tensor. In the case of a two-dimensional mean flow, which is the case
58 considered here (waves propagating with a turbulent current), the eddy viscosity can be defined
59 as the coefficient of proportionality linking Reynolds shear stress with the normal velocity
60 gradient. Dimensional analysis indicates that eddy viscosity in turbulent flows should be
61 represented by a typical velocity scale u_m and a characteristic length scale l_m. As mentioned
62 above, models based on eddy viscosity assumptions can be categorised into zero-equation
63 models, one-equation models (Davies et al., 1988), and two-equation models (Son and Andre,
64 1991; Holmedal et al., 2003; Zheng et al., 2010; Teles et al., 2012, 2013; Zhang et al., 2014;
65 Silva et al., 2016; and Zhang et al., 2017), depending on the number of differential equations
66 needed to solve the length scale and/or velocity scale explicitly.

67 Zero-equation WCI models can be placed into four classes: time-invariant eddy viscosity
68 (Lundgren, 1972; Grant and Madsen, 1979; Myrhaug, 1982; Christoffersen and Jonsson, 1985;
69 Myrhaug and Slaattelid, 1989, 1990; You et al., 1991, 1992; You, 1994; Yuan and Madsen,
70 2015); time-dependent eddy viscosity (Malarkey and Davies, 1998); mixing length (Umeyama,
71 2005, 2009); and momentum (Fredsøe, 1984). A wide variety of eddy viscosity distributions
72 have been assumed (dividing the boundary layer into two, three or four layers), together with
73 simplified boundary layer equations, to derive mathematical representations of mean velocities
74 and bed shear stress. A parameterised approach based on outputs from some of these models
75 (Grant and Madsen, 1979; Fredsøe, 1984; Christoffersen and Jonsson, 1985; Myrhaug and

76   Slaattelid, 1990) was given by Soulsby et al., 1993 and by Holmedal et al., 2000. Most of the
77   eddy viscosity distributions were assumed rather than obtained from experiments. There is thus
78   scope for a validation of eddy viscosity under combined current and oscillatory flow conditions
79   based on experiments to provide a better description of mean velocity profiles.

80   Results from many experimental studies have been published which provide an understanding
81   of wave-induced changes in the mean velocity field under combined flow, either carried out in
82   small-scale wave flumes, large-scale water tunnels, or by field tests. Laboratory results focused
83   on a combined current and oscillatory flow have been given by Bakker and van Doorn (1978),
84   Van Doorn (1981), Kemp and Simons (1982, 1983), Klopman (1994), Fredsøe et al. (1999),
85   Umeyama (2005, 2009, 2011), Yuan and Madsen (2014, 2015), Musumeci et al. (2006) and
86   Fernando et al. (2011). Field tests of bottom boundary layers in the sea have been reported by
87   Huntley and Hazen (1988), Lambrakos et al. (1988), Soulsby and Humphrey (1990), and
88   Trowbridge and Agrawal (1995). Bed shear stress under a combined flow has also been studied
89   by Simons et al. (1992), Simons et al. (1994), Simons et al. (2000), Simons and MacIver (2001),
90   and Jepsen et al. (2011). However, very few attempts have been made to use their results to
91   validate the eddy viscosity assumptions. Existing WCI models commonly use the data from
92   Bakker and van Doorn (1978), or Kemp and Simons (1982, 1983) for validation and there is
93   still a need for more experimental data on WCI to cover a wider range of wave and flow
94   conditions.

95   To summarise the paragraphs above, previous WCI models have relied heavily on eddy
96   viscosity assumptions, generally describing the boundary layer in terms of different layers.
97   Experimental studies of combined wave-current flows have been conducted to investigate the
98   changes of flow characteristics caused by WCI, but there is no consensus as to the number,
99   extent or shape of the layers for eddy viscosity profiles. This paper aims to provide new data,
100   at different scales and using a range of experimental techniques, from which a relatively simple
101   distribution of eddy viscosity can be derived, based on physical considerations and applicable
102   to cases where the oscillatory flow is induced either by waves or in a large-scale water tunnel.
103   The PIV measurements collected from the wave-current flume and the low-turbulence flume
104   for smooth boundary, laminar wave conditions were used to derive the semi-empirical formula.
105   This was validated using the data collected by LDV from the large oscillating water tunnel for
106   rough, turbulent oscillatory flow conditions. The paper will also revisit previous formulae and
107   make some comparisons. The results will be of use to researchers wishing to adopt a simple
108   description for the mean velocity profile using an eddy viscosity approach (for instance, Egan
109   et al. (2020) or Zitman and Schuttelaar (2012)).

110   The paper is organised into six parts as follows. Firstly, information describing the experiments
111   is introduced in section 2. This includes descriptions of the settings required to obtain accurate
112   experimental measurements. Section 3 presents the approach to data analysis. Next, the
113   experimental results for the large-scale oscillating water tunnel and the smaller-scale wave-
114   current flume are shown and the newly developed eddy viscosity distribution is presented in
115   section 4. Section 5 discusses the influence of the newly-developed eddy viscosity distribution
116   on the mean velocity profiles. Concluding remarks are outlined in section 6, together with some
117   implications for numerical modellers.

2. Experimental set-up and procedures

119   In the present study, experiments were performed independently in three facilities: two flumes
120   of different scale and an oscillating water tunnel. Experimental data from a range of different
121   experimental conditions have been obtained. The overall aim is to validate existing eddy
122   viscosity distributions and to provide a new semi-empirical formula.

### 2.1 Wave-current flume experiments

124   The first set of experiments was carried out in the UCL wave-current flume. This flume is 16m
125   long and 0.45m wide, with glass sidewalls and bed allowing accessibility for Laser Doppler
126   Velocimetry (LDV), Particle Image Velocimetry (PIV) and photography at the test section. The
127   velocities at the test section were measured at the centre of the flume, using a two-dimensional
128   PIV system. In the present study, the velocity vectors were measured in the vertical x-y plane,
129   giving the streamwise velocities u and vertical velocities v. The PIV measurements were
130   obtained by illuminating the vertical plane with a double-pulsed laser. The laser was fixed on a
131   rigid steel base and produced a vertical light sheet upwards through the flume bed. For each of
132   the conditions tested in the present study, 770 pairs of images covering an area of 195mm
133   ×195mm were recorded consecutively. The PIV sampling frequency for the tests lay in the
134   range 7Hz to 4Hz, depending on the wave frequency. The sampling frequency was set to aid
135   ensemble-averaging by having an integer number of values in each wave cycle. Image
136   processing leads to a spatial resolution of 1.5mm, which was fine enough to reveal detailed
137   information in the bottom boundary layers. A wave probe was positioned close to the test
138   section but not interfering with the PIV measurements, to measure the free surface elevations.
139   Collection of the wave data was triggered by the initial firing of the first laser pulse when
140   acquiring each set of 770 image pairs.

141   The experimental procedure was as follows: i. Open the valves to let the turbulent current

142   develop and then adjust to achieve the required constant water depth; ii. Allow a settling period

143   of 30-60 minutes before starting experiments; iii. Generate waves and wait for 50s before

144   collecting data; iv. Stop the wave paddles. The water depth was maintained constant by an

145   adjustable weir gate at the outlet end of the flume and adjustments of the valves. This ensures

146   the repeatability of current conditions.

147   Wave properties ranged from 0.5Hz to 1Hz in frequency and from 52mm to 138mm in height,

148   with a water depth of 0.4m. The turbulent current with a depth-averaged mean velocity of 0.175

149   m/s was generated and flowed with the waves in the same direction. Table 1 presents the

150   experimental conditions of the experiments performed in the wave-current flume. The mean

151   velocity of the unidirectional current U_c was calculated by averaging the mean velocities over

152   depth. The wave orbital velocity amplitude U_w was calculated from wave parameters using

153   second-order Stokes wave theory at the bed. The current Reynolds number was defined as

154    $Re_c = U_c \cdot h/\nu$, where h is the water depth and ν is the kinematic viscosity. The wave Reynolds

155   number based on the wave semi-orbital excursion was defined as $Re_w = U_w \cdot A_w/\nu$, where A_w

156   is the wave semi-orbital excursion $A_w = U_w \cdot T/2\pi$ at the bed. As can be seen from the tables,

157   current Reynolds numbers are higher than the critical number of 5000 (Sleath, 1984). Therefore,

158   the current boundary layers are fully turbulent. Reynolds numbers of wave boundary layers

159   based on the wave semi-orbital excursion are lower than the critical values of 1.6×10^5 as given

160   by Sleath (1984). Therefore, the wave boundary layers for all cases lie in the laminar regime.

161   For more detailed information of the experimental set-up and a summary of the flow conditions,

162   the reader is referred to Zhang and Simons, 2019. Figure 1 demonstrates the flow regimes for

163   all the tests conducted in the wave-current flume.

**2.2 Low-turbulence flume experiments**

The second set of experiments was conducted in the UCL low-turbulence flume. This is 6m long, 49.3 cm wide, 27 cm deep, fitted with a vertical plunger wave generator, and is described in Zhang and Simons (2019). The current generated had a depth-averaged mean velocity of 0.2 m/s. Waves were generated and propagated with the turbulent current, with wave properties ranging from 0.9Hz to 0.6Hz in frequency and wavemaker stroke up to 20mm. Test procedures were similar to those described above. Table 2 summarises the experimental conditions of the experiments performed in the low-turbulence flume. Figure 2 demonstrates the flow regimes for all the tests conducted in the low-turbulence flume. As shown in the figure, the current boundary layers are fully turbulent and the wave boundary layers for all cases lie in the laminar regime.

2.3 Large oscillating water tunnel experiments

The third set of experiments were carried out in the Large Oscillating Water Tunnel (LOWT) at the De Voorst Laboratory of Delft Hydraulics. The oscillating water tunnel had a working section of length 14m, a height of 1.1m, a width of 0.3m, and with cylindrical risers at each end – see Figure 3. A steel piston was located at one end of the water tunnel and was used to generate the desired oscillatory water motions, with a maximum excursion length of 4.9m at the test section. The maximum velocity amplitude was up to 1.8m/s for a wide range of wave periods

202   from 2.0s to 14.0s. A steady turbulent current was generated by two pumps, with capacities of

203   20 L/s and 100 L/s. The recirculating flow system was connected to the cylindrical risers and

204   could be isolated from the tunnel by valves. For pure oscillatory flow tests, these valves were

205   closed. The maximum capacity of the pump (100 L/s) corresponds to a depth-averaged velocity

206   of 0.42 m/s. Flow straighteners were placed at both ends of the water tunnel, and the current

207   flow was from the closed riser to the open riser.

208   The working section of the tunnel bed was covered with a 2D 'k-type' roughness, which was

209   composed of 6mm square by 300mm long elements and positioned evenly with a spacing of

210   25mm (see Figure 4). The Nikuradse equivalent sand roughness k_s was determined from the

211   mean horizontal velocity profile of the combined flow using the definition $k_s = 30 * y_0$. Here,

212 y_0 represents the bed roughness and was determined from the logarithmic law of the wall:

213    $$\frac{\overline{U}}{u_*} = \frac{1}{\kappa} \ln\left(\frac{y}{y_0}\right)$$ …………………………………………… (1)

214   where u_* represents the shear velocity (u_{*c} and u_{*wc} represent the shear velocity for current-

215   alone test and combined wave-current tests respectively). It should be noted that the progressive

216   origin shift method of Clauser (1956) was adopted to obtain an accurate determination of y_0

217   from the mean velocity profile. The origin shift ε was varied until a best fit of Equation (1) to

218   the data in the logarithmic region of the boundary layer was achieved. The lower and upper

219   limits of the logarithmic region were chosen in accordance with previous literature (for instance,

220   Stuart, 1984; Perry and Joubert, 1963). This indicates a value of $k_s = 30 * y_0 = 0.0366$m.

221   The coordinate system adopted in the present paper had the x-direction in the direction of the

222   mean current. The y-axis was directed upward vertically, with $y = 0$ being at the roughness

223   element top. It should be noted that this was not the location where the mean velocity is equal

224   to zero. The position where mean velocity is zero is a distance ε below the nominal location of

225   y=0. Previous studies of turbulent boundary layers using 2-dimensional roughness elements

226   (e.g. Perry et al., 1969) have found values for the velocity origin shift ε of between $0.7k$ and

227    $0.8k$ below the roughness crest level, where k is the roughness element height. The value was

228   observed to be $0.51k$ in the present study, in agreement with classical theories. The z-axis

229   represents the horizontal spanwise direction across the tunnel.

230   The instantaneous bed shear stress was measured by a shear cell, as described by Simons and

231   MacIver (2001). The method is based on measuring the total force on an active plate and

232   therefore directly measures shear stress under a combined flow condition. Two velocity

233   components were measured by LDV at 100Hz sampling rate. The duration of the sampling time

234   was long compared with the time scales of the characteristic wave and turbulent current. This

was done to ensure a reliable time-averaged mean value for velocity and shear stress, not biased by the phase of the wave or short-term turbulent fluctuations. Sampling durations were typically of the order of a hundred wave cycles (Table 3). The different sampling durations ensured statistically reliable data for the different periods of oscillation but was otherwise not critical. Successful measurements of velocities very near the bed were accomplished by aligning the two reference beams parallel to the channel bed with the main beam directed towards the bed. The LDV measurements gave two orthogonal velocity components at an angle of $\pm 45°$, which could be processed into u- and v- velocities.
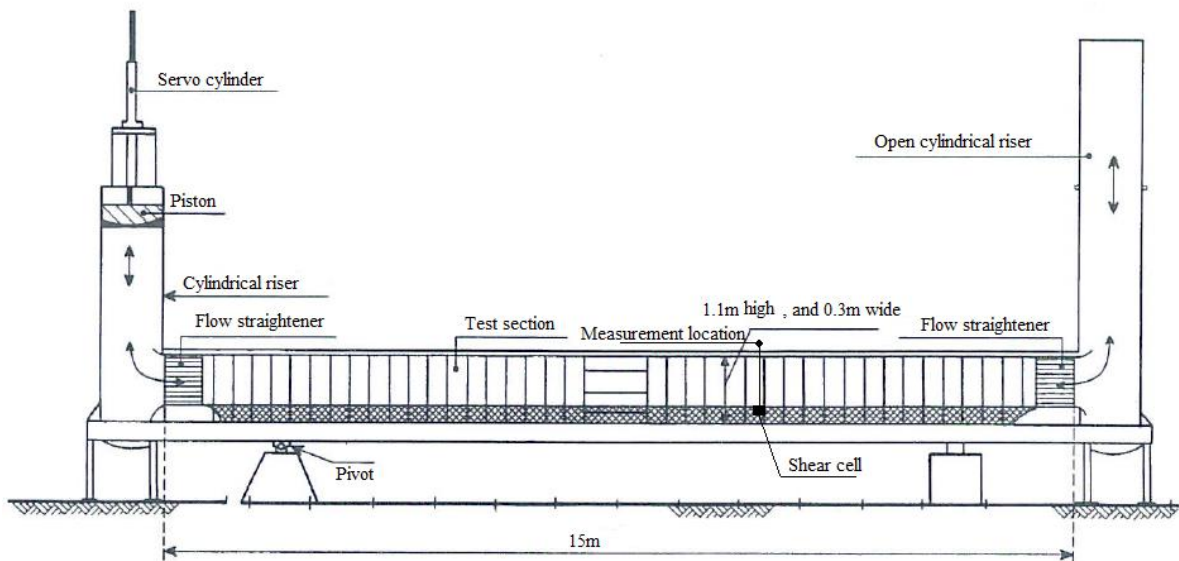

Figure 3. The Large Oscillating Water Tunnel.
Figure 4. The idealised 2D bed roughness: $k = 6mm, L = 25mm$.

9

The procedure for performing a test was as follows: i. Record the start-zero reference file; ii. Generate the required test conditions in the tunnel; iii. Start data acquisition after allowing a settling time of 10-15 min; iv. Stop tunnel and allow a settling time of 10-15min; v. Record the end-zero reference file.

The experiments performed in the oscillating water tunnel covered a large range of oscillatory Reynolds number $Re_w = U_w a_w / \nu$, where U_w is the free-stream ensemble averaged velocity amplitude of the 1st harmonic measured at the outer edge of the turbulent boundary layer (y=210.6mm), a_w is the orbital amplitude, and ν is the kinematic viscosity of water determined from the water temperature. Another important non-dimensional parameter influencing the turbulent oscillatory boundary layer is the relative roughness a_w/k_s, where k_s is the Nikuradse roughness. The test conditions are listed in Table 3. It should be noted that δ_{TBL} represents the turbulent boundary layer thickness of the unidirectional current. The value of δ_{TBL} was determined as the displacement above the bed where the Reynolds shear stress goes to zero. Figure 5 demonstrates the flow regimes for all the tests conducted in the oscillating water tunnel. Noting that the critical value of wave Reynolds number over rough beds was calculated based on Equation 2.7 from Sleath (1984). As can be seen from the table and the figure, the current boundary layers are fully turbulent and the wave boundary layers for all cases lie in the turbulent regime.

Table 3. Flow conditions for the LDV velocity profile measurements ($k_s = 0.0366m$), water depth $h = 0.8m$, current free-stream velocity $U_{\infty c} = 0.51 \ (m/s)$, depth-averaged mean velocity $U_c = 0.42$ (m/s), current Reynolds number $Re_c = U_{\infty c}\delta_{TBL}/\nu$ =102,000.

3. Data analysis method

It should be noted here that this paper is concerned only with the time-averaged mean flow kinematics (i.e. velocities and Reynolds shear stresses). Therefore, only the time-averaged components of eddy viscosity are calculated, and shear stresses due to periodic components are not presented. Methods for data analysis are described in the following sub-sections.

3.1 Turbulent fluctuations

In a combined wave and current condition, velocities are composed of wave-induced periodic components, a steady current-induced component and random turbulence fluctuations (Kemp and Simons, 1982; Nielsen, 1992). For a velocity component M (either u or v), this is expressed by the following equation:

$$M = M' + \langle M \rangle \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots(2)$$

$$\langle M \rangle = \bar{M} + \widetilde{M} \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots(3)$$

$$\bar{M} = \frac{1}{N_1} \sum_{j=0}^{N_1-1} M(j \cdot dt) \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots(4)$$

$$\widetilde{M}(t) = \frac{1}{N_2} \sum_{j=0}^{N_2-1} M(t + j \cdot T) - \bar{M}, \ \ 0 \leq t < T \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots(5)$$

where M' is the turbulence component, $\langle M \rangle$ is the sum of periodic and time-averaged velocity component, $\bar{M}$ is the time-average of M over the full sample period, N_1 represents the whole

11

291 number of measurements for time-averaging, dt is the time between two consecutive

292 measurements: $dt = 1/f$, f is sampling frequency, $\widetilde{M}$ is the periodic component, T is the wave

293 period, and N_2 is the whole number of periods for ensemble-averaging.

294 **3.1.1 Data analysis for LDV measurements**

295 For the experimental data obtained in the large oscillating water tunnel, velocity components

296 were measured by LDV. Because of the single-point measurement techniques adopted, the

297 definitions given above can be applied directly for the calculations of velocity fluctuations.

298 **3.1.2 Data analysis for PIV measurements**

299 Each PIV image has 127 grid points in the x direction. The procedure of performing ensemble-

300 averaging was different from the single-point measurement techniques. Three-point spatial

301 averaging was performed first, providing high frequency smoothing. This covered a length of

302 4.5mm, which was much smaller than the wavelength. Thus, the difference in wave-induced

303 velocities within the adjacent three points was negligible. Then, ensemble-averaged velocities

304 were obtained by averaging velocities at the same wave phase over 77 or 154 cycles. The

305 difference in the number of wave cycles for ensemble-averaging was a consequence of a

306 different sampling frequency, which was adjusted to ensure an integer number of values of

307 velocity in each wave cycle. These two steps can be mathematically represented by the

308 following equations:

309 $$M_{new}(x_i, y, t) = \frac{1}{3} [M(x_{i-1}, y, t) + M(x_i, y, t) + M(x_{i+1}, y, t)], \quad 1 < i < 127 ....(6)$$

310 $$< M(x_i, y, t) > = \frac{1}{N_2} \sum_{j=0}^{N_2-1} M_{new}(x_i, y, t + j \cdot T), \qquad 0 < t < T ....(7)$$

311 where M is either the streamwise or vertical velocity component (u or v), i is the index number

312 of longitudinal position in each PIV image, N_2 is the total number of wave cycles, y is the

313 vertical coordinate, t is the time.

314 The turbulence fluctuations are expressed as:

315 $$M(x_i, y, t)' = M(x_i, y, t) - < M(x_i, y, t) > ....(8)$$

316 **3.2 Reynolds shear stress**

317 **3.2.1 Data analysis for LDV measurements**

318 Having obtained the time histories of turbulence fluctuations, the Reynolds shear stress was

319 determined by time-averaging. This is valid for the turbulent current flow with and without

320 waves superimposed:

321 $$\overline{\tau_{Rey}}(y) = -\frac{1}{N_1}\sum_{n=0}^{N_1-1}\rho \cdot u'(y, n \cdot dt) \cdot v'(y, n \cdot dt) \text{..................................(9)}$$

322 where $\overline{\tau_{Rey}}(y)$ represents the vertical distribution of Reynolds shear stress, and ρ is the water

323 density.

3.2.2 Data analysis for PIV measurements

325 For the PIV data, the Reynolds shear stress is obtained by time-averaging and spatial-averaging.

326 Spatial averaging was used as described above to reduce noise in the data. The turbulent eddies

327 with most energy are significantly larger than the 4.5mm over which the spatial averaging is

328 done, so the effect on turbulence intensity is negligible. Differences in the longitudinal

329 distributions of Reynolds shear stress are also small, and therefore spatial averaging of PIV

330 images along the horizontal axis is adopted in the present work. The data analysis again follows

331 the previous study of Zhang and Simons (2019).

3.3 Mean velocity profiles

333 The vertical distribution of mean velocity $\overline{U}(y)$ for the LDV measurements was obtained by

334 time-averaging:

335 $$\overline{U}(y) = \frac{1}{N_1}\sum_{n=0}^{N_1-1}u(y, n \cdot dt)\text{...(10)}$$

336 The vertical distribution of mean velocity $\overline{U}(y)$ for the PIV measurements was obtained by

337 time-averaging and spatial-averaging.

338 The mean velocity gradient was determined from the time-averaged mean velocity profile using

339 discrete experimental data. Tests have been done by adopting forward, backward and central

340 difference methods to determine the velocity gradient. No significant change (<5%) in gradients

341 was observed and the backward difference method applied was defined as follows:

342 $$\left.\frac{\partial \overline{U}}{\partial y}\right|_{y=y_p} = \frac{\overline{U}|_{y=y_p} - \overline{U}|_{y=y_{p-1}}}{y_p - y_{p-1}}\text{...(11)}$$

343 where $\overline{U}|_{y=y_p}$ denotes the mean velocity at the point $y = y_p$.

344

3.4 Eddy viscosity

346 The eddy viscosity for combined wave-current flows was calculated as for a unidirectional

347 turbulent current flow using definitions such as found in Pope (2000). The original definition

348 of the eddy viscosity for a unidirectional turbulent current is given as follows, implying that

349 eddy viscosity should have six components aligned with Reynolds stresses:

350 $$-\rho\overline{u_i'u_j'} = 2\mu_t\langle S_{ij}\rangle - \frac{2}{3}\rho k\delta_{ij}\text{..(12a)}$$

13

351   where $\langle S_{ij} \rangle$ is the rate-of-strain tensor defined as $\langle S_{ij} \rangle = \frac{1}{2}\left(\frac{\partial \langle u_i \rangle}{\partial x_j} + \frac{\partial \langle u_j \rangle}{\partial x_i}\right)$, μ_t is the turbulent

352   dynamic viscosity which is related to eddy viscosity ε_t by the density of water, k is the

353   turbulence kinetic energy (TKE) given by $k = \frac{1}{2}\left[(u')^2 + (v')^2 + (w')^2\right]$, and δ_{ij} is the

354   Kronecker delta defined as $\delta_{ij} = \begin{cases} 0, & if \ i \neq j \\ 1, & if \ i = j \end{cases}$, with the suffixes i and j taking the value of 1,

355   2 or 3.

356   In the present study, only the eddy viscosity of most relevance to vertical diffusion was

357   investigated. A 2D PIV system was adopted to obtain the velocity components in the

358   streamwise and vertical directions. Thus, $\delta_{12} = 0$ and the original definition reduces to:

359     $$-\rho\overline{u'v'} = \mu_t \frac{\partial \bar{U}}{\partial y} \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \text{(12b)}$$

360   where μ_t is the turbulent dynamic viscosity which is related to eddy viscosity ε_t by the density

361   of water ρ.

362   The kinematic eddy viscosity ε_t can then be calculated as follows, based on Reynolds shear

363   stress and mean velocity gradient obtained from the discrete experimental data：

364     $$\varepsilon_t|_{y=y_p} = \frac{\overline{\tau_{Rey}}|_{y=y_p}}{\rho * \frac{\partial \bar{U}}{\partial y}|_{y=y_p}} \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \text{(13)}$$

365 ## 4. Experimental results

366 ### 4.1 Semi-empirical formula of eddy viscosity distributions

367   PIV data collected from the wave-current flume and the low-turbulence flume are described

368   below, showing profiles of mean velocity and Reynolds shear stress. These were used to

369   calculate a semi-empirical formula for eddy viscosity.

370 ### 4.1.1 Mean velocity profiles and mean velocity gradient

371   Figure 6 illustrates the vertical variation of mean velocity for all conditions tested in the wave-

372   current flume. The choice of upper and lower limits for the logarithmic-profile region has a

373   significant effect when selecting the best-fit line. Here, two main criteria were applied: i) to

374   adopt the range that gives the best logarithmic-fitting quality as judged by the coefficient of

375   determination R^2; ii) to set the upper boundary at the point where the mean velocity starts to

376   deviate from the logarithmic profile. The criterion was set that if the discrepancy between the

377   measurements and the logarithmic curve is more than 0.3%, then it was considered that the

378   mean velocity was no longer logarithmic. Results for the unidirectional current indicate that a

14

379 logarithmic region exists in the bottom 30% of the boundary layer, giving an upper limit in

380 accordance with that reported by Pope (2000). The Von Kármán constant was obtained from

381 the logarithmic law of the wall, $\bar{U} = \frac{u_*}{\kappa} \ln\left(\frac{y}{y_0}\right)$. Here, u_* represents the shear velocity

382 determined from bed shear stress measurements (u_{*c} and u_{*wc} represent the shear velocity for

383 current-alone test and combined wave-current tests respectively), and y_0 is the apparent

384 roughness, defined as the distance from the bed where the idealised logarithmic velocity profile

385 becomes zero. In the next section, it is shown that $u_{*c} = 0.0078$ (m/s). Given this value, the

386 Von Kármán constant κ=0.3. Many studies have been carried out to investigate the value of κ,

387 although the canonical theory suggests the value of 0.4. The smooth pipe flow experiments of

388 Nikuradse (1932) quote a range of κ from 0.32 to 0.43, over a variety of Reynolds numbers.

389 Generally, the results presented above demonstrate that the turbulent current in the wave-

390 current flume possesses the properties of a classical zero-pressure-gradient turbulent boundary

391 layer and that the number of independent samples is adequate to produce statistically reliable

392 results.

393 Applying the same approach to the unidirectional turbulent current condition in the low-

394 turbulence flume, the value of the Von Kármán constant $\kappa = 0.37$. This is closer to the widely

395 accepted value of 0.4. Aspect ratios, defined as the ratio of channel width to flow depth, are

396 known to determine secondary flow responses and result in different values of κ. Given that the

397 channel width of the low-turbulence flume was 0.49m and the water depth was 0.16m, the

398 aspect ratio of the low-turbulence flume tests is 3. Therefore, secondary flows are weaker.

399 When waves are superimposed on the current, the most striking feature is that mean velocities

400 are increased near the bed and decreased in the upper flow, as observed from earlier studies on

401 wave-current interaction. The existence of logarithmic mean velocity profiles in combined

402 wave-current flows is observed (shown by the blue lines in figure 6) in line with previous

403 experiments reported for wave-current interaction (e.g., Trowbridge and Agrawal, 1995; Yuan

404 and Madsen, 2015).

405 The mean velocity gradient is a key parameter in calculating experimental values for the eddy

406 viscosity. Figure 7 shows the variations of mean velocity gradient versus the height above the

407 bed in the wave-current flume, calculated using Equation (11). A consistent and substantial

408 decrease in $d\bar{U}/dy$ caused by the waves is found in the outer flow region, while in the vicinity

409 of the bed, $d\bar{U}/dy$ increases. The wave-induced reduction in the mean velocity gradient in the

410 upper part is also observed in the low-turbulence flume and is in agreement with previous

411 studies (e.g., Kemp and Simons, 1982; Klopman, 1994).
Figure 6. Mean velocity profiles of all test conditions in wave-current flume, water depth $h = 0.4m$, flow rate of 0.178 (m/s), semi-logarithmic scale: 'CAA' for the current-alone test; others for the combined wave-current tests.

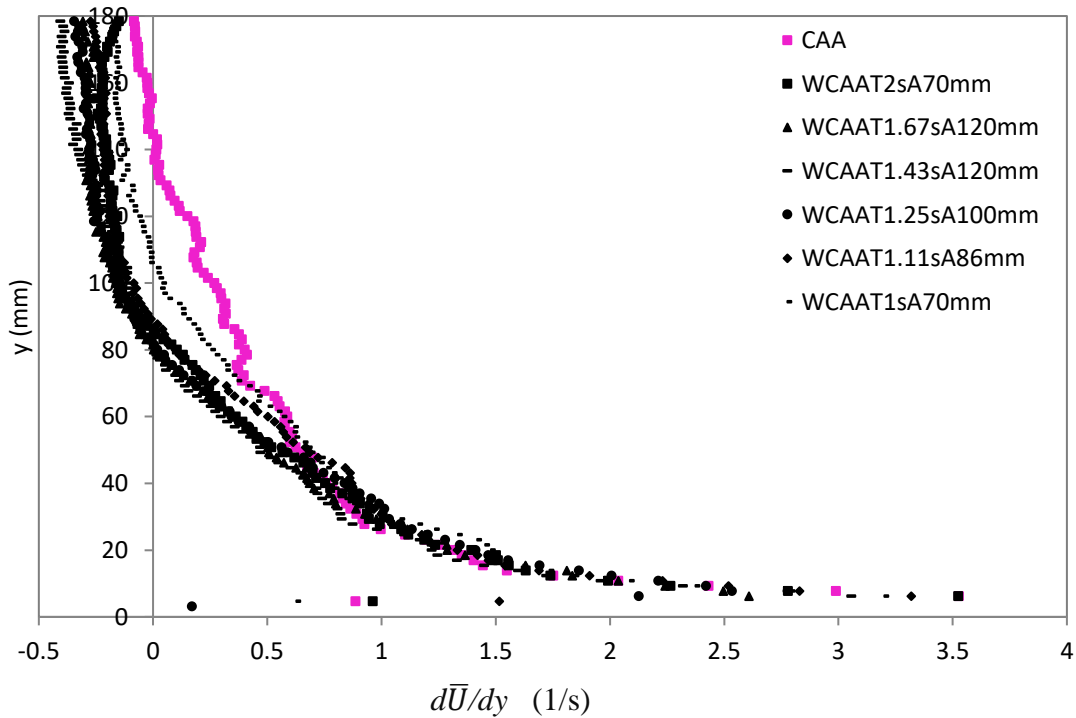

Figure 7. Vertical distribution of mean velocity gradient, all test conditions in the wave-current flume, water depth $h = 0.4m$, flow rate of 0.178 (m/s).

16

4.1.2 Reynolds shear stress

An example of the bed shear stress and characteristic boundary layer length scale determination is given in Figure 8. Classical theory of turbulent boundary layers (Pope, 2000) indicates a linear distribution of Reynolds shear stress above the bottom viscous sublayer, based on the balance of forces. This is represented as $\tau(y) = \tau_{bc}(1 - y/\delta_c)$ and $\tau(y) = \tau_{bwc}(1 - y/\delta_{wc})$, where y represents the height above the smooth bed, τ_{bc} and τ_{bwc} are the bed shear stresses for the current-alone tests and for the combined wave-current tests respectively, δ_c and δ_{wc} are the characteristic boundary layer length scales for the current-alone tests and for the combined wave-current tests respectively. Applying the best-fit curve-fitting principle and using the aforementioned definitions, the characteristic boundary layer length scale is obtained as the height above the bed where Reynolds shear stress tends to zero. As can be seen, the linear fit is valid from around y=10mm. This is in agreement with classical theories of turbulent boundary layers. In the overlap region ($y^+ = \frac{y \cdot u_*}{\nu} > 50$ and $y/\delta_c < 0.1$), viscous and turbulent stresses are both important. The shear velocities for all tests are then calculated using the definition $u_{*c} = \sqrt{\frac{\tau_{bc}}{\rho}}$ and $u_{*wc} = \sqrt{\frac{\tau_{bwc}}{\rho}}$. Values of bed shear stress and characteristic boundary layer length scale are tabulated in Table 4 for those in the wave-current flume.

Figure 8. Vertical distribution of Reynolds shear stress and bed shear stress determination for the combined flow: T=1.11s, A=86mm, $h = 0.4m$, flow rate of 0.178 (m/s).

445

4.1.3 Eddy viscosity

By analogy with the eddy viscosity concept in a unidirectional turbulent current, shear velocity can be used as the characteristic scaling parameter for non-dimensionalisation in wave-current flows. Physically, shear velocity is related to the orbital velocity of the vortices that create the turbulent mixing, exchange of particles and the momentum transfer across the boundary layer. It should be noted that the length scale for non-dimensionalisation adopted here is slightly different from previous studies of eddy viscosity. For a unidirectional turbulent current flow, Nezu and Rodi (1986) and Teles et al. (2013) used the water depth h as the scaling parameter. Previous models of wave-current interaction (Grant and Madsen, 1979; Christoffersen and Jonsson, 1985; You et al., 1991; Yuan and Madsen, 2015) also adopted the water depth as the scaling parameter for eddy viscosity, mainly because they assume a fully developed boundary layer with a high Reynolds number. However, in the present studies, a relatively low Reynolds number is involved, the flow is not always fully developed, and the addition of waves reduces the boundary layer thickness further. Therefore, the characteristic boundary layer length scale (δ_c and δ_{wc}) is more appropriate. This is demonstrated in Figure 9 and will be further discussed later.

The adoption of the velocity and length scales for the non-dimensionalisation of eddy viscosity as described above is consistent with classical turbulent boundary layer theory. Assuming that the velocity profile obeys the logarithmic law of the wall and that the Reynolds shear stress has a linear distribution, the kinematic eddy viscosity can be represented as $\varepsilon_t = \kappa \cdot u_* \cdot y \cdot (1 - y/\delta)$. Note that u_* is the shear velocity (u_{*c} for the current-only test and u_{*wc} for the combined wave-current condition), and δ represents the characteristic boundary layer length scale (δ_c for

468 the current-alone test and δ_{wc} for the combined wave-current condition). Thus, the non-

469 dimensionalised eddy viscosity is found to be:

470 $$\varepsilon_t^+ = \frac{\varepsilon_t}{u_* \cdot \delta} = \kappa \cdot \frac{y}{\delta} \cdot \left(1 - \frac{y}{\delta}\right) \quad \text{...(14)}$$

471 In the vicinity of the bed where the constant stress assumption is appropriate, the eddy viscosity

472 should tend to a constant value (kinematic viscosity). However, in the fully turbulent regions

473 of the boundary layer, the last term in Equation (14) is left out and the non-dimensional eddy

474 viscosity is simplified as (Nielsen, 1992):

475 $$\varepsilon_t^+ = \kappa \cdot \frac{y}{\delta} \quad \text{..(15)}$$

476 In this paper these two equations will be referred to as the analytical approach. The applicability

477 of the equations is examined below.

478 The analytical approach agrees well with experimental results from the low-turbulence flume

479 tests (Figure 9(a)); a linear distribution in the near-bed region and a parabolic one in the upper

480 part of the water column with the transition point at $\frac{y}{\delta} = 0.1$. The value of the Von Kármán

481 constant was determined from mean velocity profiles and Reynolds shear stress distributions.

482 Reynolds shear stress estimation is presented in section 4.1.2. As can be seen from figure 9(b),

483 results of eddy viscosities when non-dimensionalised using the water depth show considerable

484 scatter and no clear linear and parabolic distributions. Figures 9(a) and 9(b) confirm that the

485 characteristic boundary layer length scale is more appropriate than the water depth as the length

486 parameter for non-dimensionalisation in the present study.

487

488
489
490

491   Figure 9. Distributions of non-dimensional eddy viscosity, tests conducted in the low-
492   turbulence flume: (a) non-dimensionalised using the characteristic boundary layer length
493   scales; (b) non-dimensionalised using the water depth.

494

495   However, the analytical approach does not always provide good agreement with experimental

496   results from the wave-current flume tests. The experimental distribution of non-dimensional

497   eddy viscosity appears to follow one of two types dependent on the relative strength of waves

498   and currents, using the parameter adopted by Soulsby et al. (1993): type I (current-

499 dominated: $0.5 < \frac{\tau_c}{\tau_c + \tau_w} < 1$); and type II (wave-dominated: $0 < \frac{\tau_c}{\tau_c + \tau_w} \leq 0.5$) (Figure 10).

500 The classification method was found to be in agreement with the previous study of Soulsby et

501 al. (1993). In type I case conditions, the analytical approach provides a satisfactory agreement

502 (Figure 10(a)): a linear distribution in the near-bed region and a parabolic one in the upper part,

503 although there is some discrepancy. This may be caused by the fact that the boundary layer is

504 still developing and from weak effects of the waves on the mean velocity gradient. The case for

505 the current-alone condition lies in the first type. This is expected because unidirectional

506 turbulent current can be considered as a limiting case. In type II case conditions, the analytical

507 approach breaks down for $\frac{y}{\delta} \geq 0.4$ (Figure 10(b)). A linear distribution is observed in the

508 experimental data in this region, represented as $\varepsilon_t^+ = a \cdot \left(\frac{y}{\delta}\right) + b$. To avoid a discontinuity at

509 $\frac{y}{\delta} = 0.4$, the fitted curve is forced through the fixed point where $\frac{y}{\delta} = 0.4$ and $\varepsilon_t^+ = 0.24\kappa$, based

510 on Equation (14). At the upper edge of the boundary layer, the non-dimensional eddy viscosity

511 ε_t^+ is observed to have a value of 0.03 rather than the value of zero given by the analytical

512 approach (plotted using the red line). Therefore, the coefficients a and b can be expressed as

513 functions of the Von Kármán constant: $a = 0.05 - 0.4\kappa$; $b = 0.4\kappa - 0.02$.

514 Based on the findings above, the newly developed semi-empirical formula for non-dimensional

515 eddy viscosity is represented as follows:

516 i). Type I (current-dominated)

517
$$\varepsilon_t^+ = \begin{cases} \kappa \cdot \left(\frac{y}{\delta}\right) & \frac{11.6\nu}{u_*} < \frac{y}{\delta} \leq 0.1 \\ \kappa \cdot \frac{y}{\delta} \cdot \left(1 - \frac{y}{\delta}\right) & 0.1 \leq \frac{y}{\delta} \leq 1 \end{cases} \quad\dots\dots\dots\dots\dots\text{(16-a)}$$

518 ii). Type II (wave-dominated)

519
$$\varepsilon_t^+ = \begin{cases} \kappa \cdot \left(\frac{y}{\delta}\right) & \frac{11.6\nu}{u_*} < \frac{y}{\delta} \leq 0.1 \\ \kappa \cdot \frac{y}{\delta} \cdot \left(1 - \frac{y}{\delta}\right) & 0.1 \leq \frac{y}{\delta} \leq 0.4 \\ a \cdot \left(\frac{y}{\delta}\right) + b & 0.4 \leq \frac{y}{\delta} \leq 1 \end{cases} \quad\dots\dots\dots\dots\text{(16-b)}$$

520 where: $a = 0.05 - 0.4\kappa$; $b = 0.4\kappa - 0.02$.

521 The equations summarised above have implications for the structure of turbulence in wave-

522 current interaction. When the waves superimposed are relatively small, their effect on the

523 current is weak. The influence of the waves is apparent in the changes to shear velocities and

524 boundary layer thickness, which are embedded in the non-dimensionalisation analysis of eddy

525 viscosities. Therefore, non-dimensional eddy viscosity distributions have the same

526 mathematical representation as those of unidirectional turbulent currents. However, under

527 conditions with large waves, re-laminarisation can occur as explained in the investigation of

528 Lodahl et al. (1998). Turbulence in the outer region is significantly inhibited by the waves and
529 the processes of turbulent mixing are inhibited accordingly. This leads to a linear distribution
530 of non-dimensional eddy viscosity.
531
532

533 Figure 10. Distributions of non-dimensional eddy viscosity, tests conducted in the wave-
534 current flume: (a) type I; (b) type II.

535

536 A comparison with other eddy viscosity distributions is presented in Figure 11. Note that the

537 Grant and Madsen (1979) model uses the formula: $\varepsilon_t = \begin{cases} \kappa \cdot u_{*wc} \cdot y &, \ y > \delta_w \\ \kappa \cdot u_{*wcm} \cdot y &, \ y < \delta_w \end{cases}$ where δ_w

538 represents the wave boundary layer thickness and $u_{*wcm} = \sqrt{\tau_{bmax}/\rho}$ with τ_{bmax} for the

539 maximum value of bed shear stress within one wave cycle. Results show that the model of

540 Grant and Madsen (1979) overestimates the eddy viscosity in the outer flow. The model of

541 Yuan and Madsen (2015) was a modification of Grant and Madsen (1979) avoiding the

542 discontinuity of eddy viscosity between the inner and outer layers. Hence, the general shape is

543 the same as for Grant and Madsen (1979) and therefore is not included here. The model given

544 by Christoffersen and Jonsson (1985), for a relatively small roughness (named as 'Model II' in

545 their original paper), is presented as the 'Christoffersen and Jonsson (1985) – original' in the

546 figure. The values predicted using their model were calculated by the formula: $\varepsilon_t =$

547 $\begin{cases} \kappa \cdot y \cdot u_{*wc} \cdot (1 - y/h) &, \ \delta_w < y < h \\ \kappa \cdot u_{*wcm} \cdot y &, \ y \leq \delta_w \end{cases}$. This model again overestimates the observed eddy

548 viscosity distribution in the outer flow in the present data. This is because the Christoffersen

549 and Jonsson (1985) model assumes eddy viscosity has a parabolic distribution throughout the

550 water depth, while the present experimental data indicate that the length scale for the combined

551 flow should be the thickness of the boundary layer. However, the Christoffersen and Jonsson

552 (1985) model is based on a fully developed boundary layer assumption, which is not the case

553 in the present study. The 'Christoffersen and Jonsson (1985) – Adapted' plot in Figure 11 re-

554 scales their original model using the observed characteristic boundary layer length scale. This

555 shows their model to work well near the bed, but to differ slightly from the present formula in

556 the upper region. It should be noted that the Grant and Madsen (1979) model does not contain

557 the water depth in their formula, hence their model cannot be re-scaled in the same way as the

558 adapted version of Christoffersen and Jonsson (1985).

559 Although there has been debate as to whether turbulent eddy viscosity in an oscillatory flow

560 should be time-invariant or time-dependent, the experimental data presented here suggest that

561 a time-invariant eddy viscosity model can describe mean flow kinematics in most cases in a

562 combined wave-current flow. However, it should be noted that if a prediction of second order

563 drift quantities such as streaming is required, a time-dependent turbulent boundary layer needs

564 to be modelled and then averaged. In that case, a time-dependent eddy viscosity is necessary.

565 A time-independent eddy viscosity best reflects the turbulent coherent structures and vortices

566 that persist within the boundary layer. Turbulent loops under the effects of wave motions

567 convect with the mean flow, and may also undergo deformations during deceleration and
568 acceleration phases. Although these turbulent vortices may vary in scale within one wave cycle,
569 the shape of the turbulent boundary layer is retained. Previous research (e.g., Grant and Madsen,
570 1979; You et al., 1991; Yuan and Madsen, 2015) has pointed out that a time-varying eddy
571 viscosity would call for numerical approaches rather than analytical methods, in order to solve
572 the governing equations. Therefore, in a practical sense, the adoption of a time-varying eddy
573 viscosity for two-dimensional and three-dimensional simulations would be demanding on
574 computational resources.
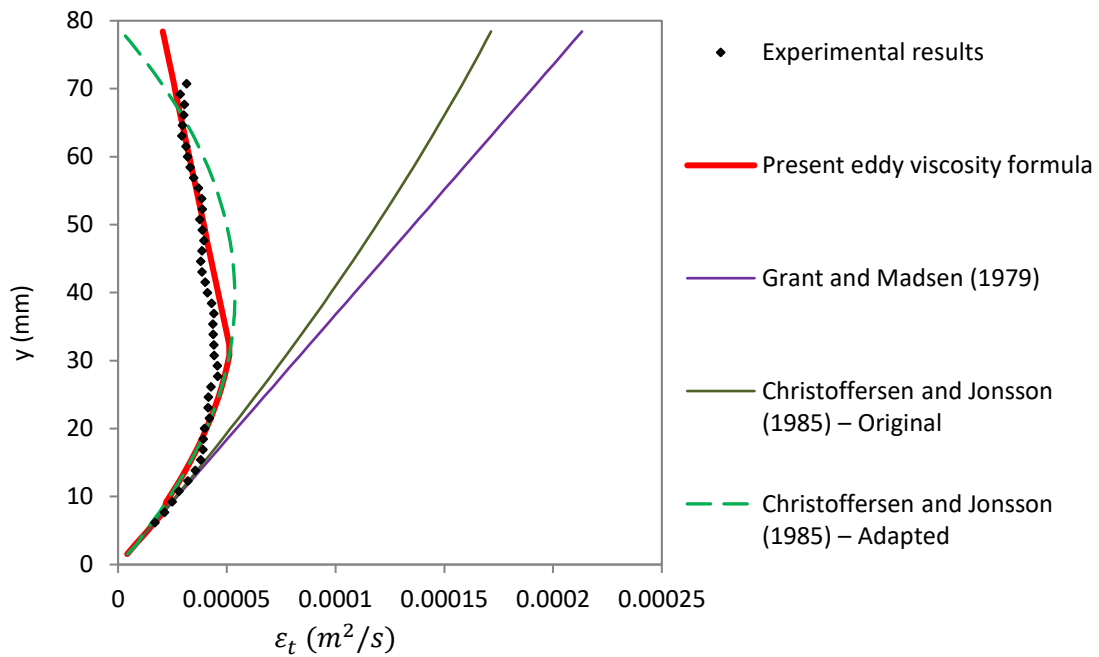

575

576 Figure 11. Eddy viscosity distribution of combined wave-current flow:

579 **4.2 Validation of the semi-empirical formula**

580 In order to investigate the wider validity of the present semi-empirical formula (Equations 16-
581 a and 16-b), a comparison has been made with the experimental results from the large oscillating
582 water tunnel tests. These tests considered combined wave-current flows with high wave-
583 Reynolds number over a wide range of oscillatory periods (2.75s to 9.5s) and amplitudes (0.24m
584 to 0.62m) (Table 3). Note that all conditions lie within the type II eddy viscosity distribution.
585 The present semi-empirical formula for eddy viscosity was proposed for combined flows over
586 a smooth bed. However, the comparison shown in Figure 12 demonstrates that it is also valid
587 for flows over rough boundaries. This is consistent with work by Grass (1971) which showed

588 that the turbulent boundary layer above the near-bed layer is the same over smooth and rough

589 beds.

590 It should be noted that: the eddy viscosity was normalised by the product of the characteristic

591 length scale δ_{wc} and the shear velocity u_{*wc} of the combined wave-current flow obtained

592 directly from the shear plate; the height above the roughness element crest was normalised by

593 the characteristic length scale to show the relative vertical position within the boundary layer;

594 and, the Von Kármán constant was found to be 0.3 by applying the logarithmic law.

595 The combined flows in an oscillating water tunnel simulate many aspects of wave-current flow

596 in the lower part of the boundary layer at near full-scale ocean conditions. Oscillating water

597 tunnels can generate large orbital amplitudes and oscillation periods, with great control,

598 producing high wave-Reynolds number flows similar to ocean conditions, thereby overcoming

599 several physical limitations inherent in laboratory-scale wave flumes. This feature makes it

600 reasonable to generalise the present findings and consider the proposed semi-empirical formula

601 is applicable to real ocean sites.
602

604 the Large Oscillating Water Tunnel.

605

5. Discussions

The consequence for the mean velocity profile of the different eddy viscosity distributions plotted in Figure 11 is shown in Figure 13, based on the governing equation $\frac{\partial \bar{U}}{\partial y} = \frac{(u_{*wc})^2 \ (1-y/h)}{\varepsilon_t}$ or $\frac{\partial \bar{U}}{\partial y} = \frac{(u_{*wc})^2 \ (1-y/\delta_{wc})}{\varepsilon_t}$. It should be pointed out here that the first equation is in the same form as given by You (1994), while the second one is found by substituting the typical length scale δ_{wc} for water depth h. The first equation was derived by combining the two basic equations:

$$\tau(y) = \rho(u_{*wc})^2 \left(1 - \frac{y}{h}\right) \ \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \ (17)$$

$$\frac{\tau(y)}{\rho} = \varepsilon_t \cdot \frac{\partial \bar{U}}{\partial y} \ \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \ (18)$$

For those models where a fully developed turbulent boundary layer is assumed, the first equation is adopted. For the other models, the change is made because Reynolds shear stress reaches zero at the edge of the boundary layer rather than at the free surface.

The figure demonstrates that, in the lower water column, the mean velocities predicted using the eddy viscosity distributions of Grant and Madsen (1979), Christoffersen and Jonsson (1985) and the distribution proposed here are all in good agreement with the experimental data obtained from the wave-current flume.

However, above $y^+ = 300$, the velocity profiles predicted using the eddy viscosity distributions from Grant and Madsen (1979) and Christoffersen and Jonsson (1985) both underestimate the observed mean velocity. This is explained by the divergence of values for ε_t in the upper water column, as shown in Figure 11.

Mean velocities predicted using the adapted version of Christoffersen and Jonsson (1985) are also observed to underestimate the experimental results. This is not surprising since although the adapted version of their model is based on the characteristic length scale of the boundary layer, the parabolic distribution of eddy viscosity mathematically leads to a logarithmic velocity profile. Therefore, this distribution cannot accurately describe the mean velocity profile for those regions where logarithmic laws are not obeyed.

It should be pointed out here that although the discrepancy between the mean velocity profiles determined from different eddy viscosity distributions is not large, the eddy viscosity distribution proposed in this paper is more accurate for describing the flow kinematics in the upper flow region.

637
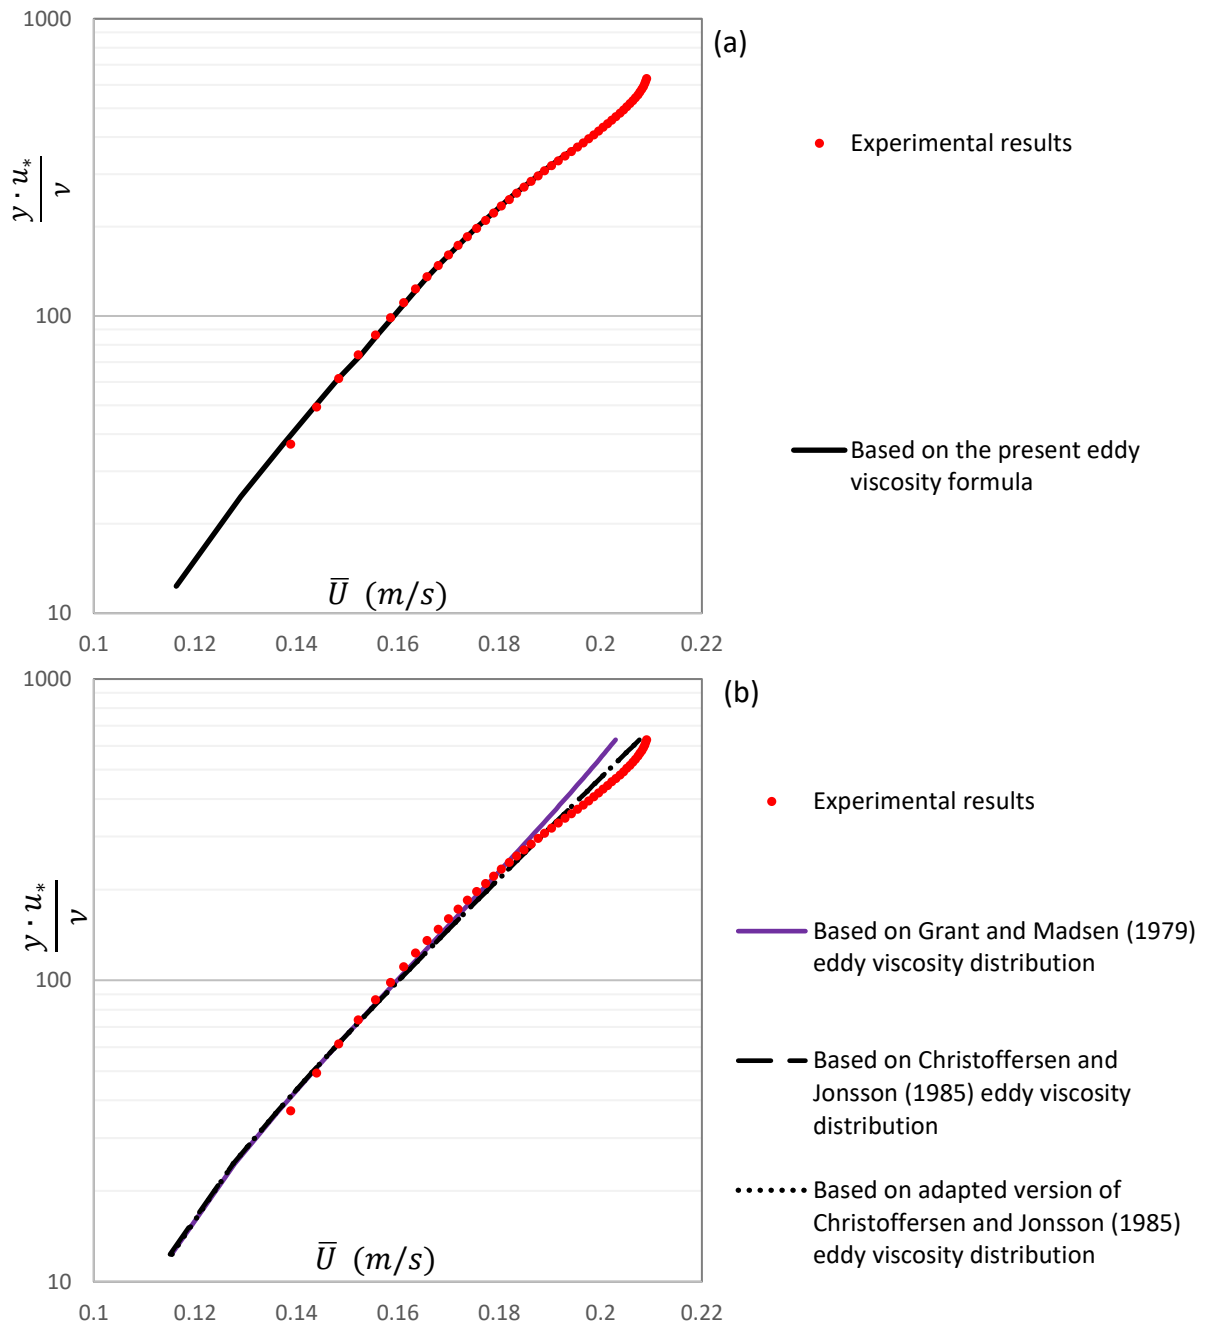

638
639   Figure 13. Intercomparison of the mean velocity profiles, based on various eddy viscosity
640   assumptions. Combined flow over a smooth bed, T=1.11s, A=86mm, $h = 0.4$m, flow rate of
641   0.178 (m/s), wave-current flume: (a) based on the present eddy viscosity formula; (b) based
642   on previous eddy viscosity assumptions.

643

6. Concluding remarks

645   Results from experiments in three different facilities, a large oscillating water tunnel and two
646   wave-current flumes, have been analysed. A new semi-empirical formula has been put forward
647   for the eddy viscosity distribution in a combined wave-current flow. Experimental results from
648   the oscillating water tunnel have been used to validate the formula and suggest robust

649 performance. This new eddy viscosity distribution has been shown to represent real conditions

650 better than previous eddy viscosity assumptions. Its range of validity includes both small-scale,

651 low Reynolds number, and large-scale, high Reynolds number conditions and is applicable over

652 smooth and rough boundaries.

653 An important application of the proposed eddy viscosity distribution is giving guidance to

654 numerical modellers. The proposed eddy viscosity distribution is valuable for large-scale

655 simulations of coastal flow, including sediment transport, where solving the detailed seabed

656 boundary layer using two-equation models (e.g. $k - \varepsilon$ and $k - \omega$ models) is not practical due

657 to the large computational effort that would be required in three-dimensional simulations. Here

658 we should emphasize that the eddy viscosity model proposed in this paper is for the mean flow.

659 It does not give an instantaneous eddy viscosity related to the wave phase (e.g., during the

660 passage of a wave crest), which would vary with time.

661 Another important application of eddy viscosity is in sediment transport. The sediment

662 diffusion coefficient is related to the eddy viscosity profile, and therefore a more accurate

663 mathematical representation is significant in calculating the vertical diffusion coefficient of any

664 suspended sediment.

665 **List of Symbols**

Symbol	Description
U_w	Amplitude of streamwise velocity just outside the bottom oscillatory boundary layer
a_w	Orbital amplitude of fluid just outside the bottom oscillatory boundary layer
Re_w	Amplitude Reynolds number
U_c	Depth-averaged mean velocity
$U_{\infty c}$	Current free-stream velocity
Re_c	Current Reynolds number
T	Wave period
H	Wave height
L	Wave length
A	Wave amplitude
a	Coefficient, represented as a function of the Von Kármán constant
b	Coefficient, represented as a function of the Von Kármán constant
κ	Von Kármán constant
k_s	Nikuradse roughness parameter

Symbol	Description
ε_t	Eddy viscosity
h	Water depth
i	Index number of positions in the x direction
M	Instantaneous velocity component (representing u, v, or w)
u	Instantaneous streamwise velocity
v	Instantaneous vertical velocity
w	Instantaneous spanwise velocity
N_1	Number of measurements for time-averaging
N_2	Number of periods for ensemble-averaging
dt	Time between two consecutive measurements
t	Time sequence
f	Sampling frequency
x	Horizontal displacement
	Vertical displacement above the bed
z	Transverse displacement
M_{new}	Spatially averaged velocities within three adjacent points in the x direction
ρ	Density of water
ν	Kinematic viscosity of water
$\overline{U}$	Mean velocity
$\langle S_{ij} \rangle$	Rate-of-strain tensor
μ_t	Turbulent dynamic viscosity
δ_{ij}	Kronecker delta
k	Turbulence kinetic energy (TKE)
u_*	Shear velocity, either in a current-alone condition (u_{*c}) or a combined wave-current flow (u_{*wc}).
u_{*wcm}	Maximum value of shear velocity within one wave cycle
R^2	Coefficient of determination
$\overline{\tau_{Rey}}$	Reynolds shear stress
τ_b	Bed shear stress, either in a current-alone condition (τ_{bc}) or a combined wave-current flow (τ_{bwc}).
τ_{bmax}	Maximum value of bed shear stress within one wave cycle
δ_w	Wave boundary layer thickness
δ_c	Characteristic boundary layer length scale of the unidirectional current

Symbol	Description
δ_{wc}	Characteristic boundary layer length scale of the combined wave-current flows
ε_t^+	Non-dimensional eddy viscosity

666

Operators	Description
$\overline{M}$	Time-average of M over the whole sampling period
M'	Turbulence fluctuations component of M
$\widetilde{M}$	Periodic component of M with $\overline{\text{M}}$ subtracted
$\langle M \rangle$	Ensemble-average of M
