Summary

Dyskeratosis congenita (DC) is an inherited bone-marrow-failure disorder characterized by a triad of mucocutaneous features that include abnormal skin pigmentation, nail dystrophy, and oral leucoplakia. Despite the identification of several genetic variants that cause DC, a significant proportion of probands remain without a molecular diagnosis. In a cohort of eight independent DC-affected families, we have identified a remarkable series of heterozygous germline variants in the gene encoding thymidylate synthase (TYMS). Although the inheritance appeared to be autosomal recessive, one parent in each family had a wild-type TYMS coding sequence. Targeted genomic sequencing identified a specific haplotype and rare variants in the naturally occurring TYMS antisense regulator *ENOSF1* (enolase super family 1) inherited from the other parent. Lymphoblastoid cells from affected probands have severe TYMS deficiency, altered cellular deoxyribonucleotide triphosphate pools, and hypersensitivity to the TYMS-specific inhibitor 5-fluorouracil. These defects in the nucleotide metabolism pathway resulted in genotoxic stress, defective transcription, and abnormal telomere maintenance. Gene-rescue studies in cells from affected probands revealed that post-transcriptional epistatic silencing of TYMS is occurring via elevated *ENOSF1*. These cell and molecular abnormalities generated by the combination of germline digenic variants at the *TYMS-ENOSF1* locus represent a unique pathogenetic pathway for DC causation in these affected individuals, whereas the parents who are carriers of either of these variants in a singular fashion remain unaffected.

Introduction

A clinically diagnosed individual with dyskeratosis congenita (DC [MIM: 305000]) classically presents with a combination of muco-cutaneous features comprising abnormal skin pigmentation, nail dystrophy, and oral leucoplakia,¹ as initially described by Zinsser in 1910.² Bone-marrow failure, predisposition to cancer, and pulmonary abnormalities are reported to be major causes of death in DC-affected individuals. Inheritance of DC can be autosomal dominant, autosomal recessive, or X-linked recessive.

A major subset of individuals ($n = 17$) with DC have variants in genes that have a principal role in telomere maintenance (*DKC1* [MIM: 300126], *TERC* [MIM: 602322], *TERT* [MIM: 187270], *NOP10* [MIM: 696471], *NHP2* [MIM: 606470], *TINF2* [MIM: 604319], *WRAP53* [MIM: 612661], *CTC1* [MIM: 613129], *RTEL1* [MIM: 608833], *ACD* [MIM: 609377], *PARN* [MIM: 604212], *NAF1* [MIM: 617868], *STN1* [MIM: 6132128], *MDM4* [MIM: 602704], *ZCCHC8* [MIM: 616381], *POT1* [MIM: 606478], and *RPA1* [MIM: 179835]).¹ Five of these genes encode components

of the enzyme telomerase (*TERC*, telomerase RNA component; *TERT*, telomerase reverse transcriptase; *DKC1*, dyskerin pseudouridine synthase 1; *NOP10*, *NOP10* ribonucleoprotein; or *NHP2*, *NHP2* ribonucleoprotein) contributing to its catalytic function. Poly (A)-specific ribonuclease (PARN), zinc finger CCHC-type containing 8 (ZCCHC8), and nuclear assembly factor 1 ribonucleoprotein (NAF1) are involved in *TERC* maturation.^{3–5} *TERF1*-interacting nuclear factor 2 (TIN2), telomerase recruitment factor (ACD, also known as *TPP1*), and protection of telomeres 1 (POT1) are components of the shelterin complex that protects the telomeric DNA and is involved in telomerase recruitment and processivity.^{6–8} WD-repeat-containing antisense to TP53 (WRAP53) is important in telomerase trafficking.⁹ Telomere replication complex component 1 (CTC1) and STN1 subunit of CST complex (STN1), subunits of the CST-complex-regulated C strand, fill in at telomere ends and further facilitate recruitment and docking of telomerase onto the telomere.^{10,11} Regulator of telomere elongation helicase 1 (RTEL1) has a critical role in telomere replication and in dismantling the t loop at telomeres.¹² *MDM4*, which

encodes a major negative regulator of P53 protein, has transcriptional control of genes involved in telomere biology.¹³ Replication protein A 1(RPA1) is the largest subunit of the DNA replication protein complex that binds to single-stranded DNA and facilitates protein-protein interactions during DNA replication.¹⁴ Although the major molecular function of these genes is in telomere maintenance, it is important to recognize their multifunctional roles. For example, dyskerin, NOP10, NHP2, PARN, and NAF1 are all involved in modification and processing of ribosomal RNA for ribosome biogenesis.

In a subset of individuals with DC, germline defects are observed in genes whose major role is not in telomere maintenance. This includes germline nucleophosmin 1 (NPM1 [MIM: 164040]) variants that affect 2'-O-methylation of rRNA and modulate translation¹⁵ and U6 small nuclear RNA biogenesis phosphodiesterase 1 USB1 [MIM: 613276] that is involved in oligouridylation of U6 small nuclear RNA.^{16,17} Given the considerable heterogeneity in the disease spectrum, the uncharacterized DC individuals held in the Dyskeratosis Congenita Registry in London might harbour constitutional mutations or variants in several genes. Here we report the first evidence of a digenic inheritance pattern in a series of individuals who come from eight unrelated families and have homogeneous DC features caused by germline variants in the TYMS-ENOSF1 locus.

Material and Methods

Sequencing and bioinformatics

Genomic DNA was extracted from peripheral blood samples (Puregene, Qiagen). Exome data were processed and called jointly with a set of 2,500 whole-exome-sequenced internal control samples (UCL-ex consortium) and hg19 as a reference index (UCSC browser) according to the recommendations from the Genome Analysis Toolkit (GATK v3.2) to minimize artefactual batch effects.¹⁸ All variants identified were validated by Sanger sequencing. We then targeted the genomic region corresponding to chr18: 623000–716000 by using the Cell3 Target (Nonacis) custom kit to search for any additional variants that were not detected by the exome capture. The resultant targeted fragments were then sequenced on the Illumina MiSeq platform. Read alignment, variant calling, and annotation were performed with an in-house pipeline involving the Burrows Wheeler aligner, the Genome Analysis Tool kit, and ANNOVAR, respectively. We used IntaRNA version 2.4.1¹⁹ to predict RNA-RNA interaction by using the computational pipeline previously described, and the accurate 2D interaction prediction was performed with RactIP.²⁰

Cell culture and treatments

HeLa cells were cultured in Dulbecco's modified Eagle's medium (DMEM), and Epstein-Barr-virus-transformed lymphoblastoid lines (LCLs) were acquired from affected and unaffected individual blood samples and grown in RPMI1640. All culture media were supplemented with 10% (v/v) fetal bovine serum (FBS; HyClone), 100 IU/mL penicillin, and 100 mg/mL streptomycin (Invitrogen). Cells were maintained at 37°C in a humidified incubator

with 5% CO₂. Cell cultures were supplemented with 5-fluorouracil and hydroxyurea over a specified dose range (Sigma-Aldrich). After a 24 h incubation at 37°C, tetrazolium salt WST-1 dye (Merck Millipore) was added to the cell suspension, and the cells were analyzed on a plate reader at 450 nM absorbance (Becton Dickinson). The lentiviral induction was performed with cDNAs encoding *GFP*, *GFP*-tagged *TYMS* (Origene), and *ENOSF1* shRNA (Santa Cruz Biotechnology), in control and probands' cells by spinfection in the presence of polybrene (10 µg/mL). 8 h after transduction, media were replaced, and cells were processed for downstream analysis 24 h later.

Immunoblotting and immunocytochemistry

We prepared protein extracts by lysing washed cells in denaturing buffer (9 M urea, 150 mM 2-mercaptoethanol, and 50 mM Tris-HCl [pH 7.3]) and subsequently sonicating them to shear genomic DNA. Total and phosphorylated forms of ATM, ATR, and DNA-PK were separated on 3%–8% Tris glycine mini gels (Life Technologies). For all other proteins, 4%–12% NuPAGE Bis-Tris mini gels (Life Technologies) were used. Gels were transferred onto PVDF membrane (GE Healthcare). Blotting was performed with primary antibodies (Table S1), and the corresponding alkaline-phosphatase-conjugated secondary antibodies were supplied in the WesternBreeze chemiluminescent kit (Thermo Fisher). α-tubulin, β-actin, and GAPDH antibodies were used as a loading control. For immunocytochemistry, normal and proband cells were subjected to cytospin on poly-D-lysine-coated slides (Sigma), fixed with 4% PFA, and permeabilized with 0.1% Triton X-100 (TX100) in PBS. Fixed cells were quenched in 50 mM NH₄Cl and blocked in 10% goat serum and 1% BSA in PBS containing 0.05% TX100 for 1 h. Cells were incubated with γ-H2AX primary antibody followed by Alexa-Fluor-488-conjugated secondary antibody (Invitrogen) in blocking solution. Cells were washed three times in PBS containing 0.05% TX100 between primary and secondary antibody incubations and mounted with Vectashield containing DAPI (Vector Labs). A Zeiss LSM700 confocal microscope with ZEN software was used, and 63× captured images were acquired.

Quantification of mRNA levels by RT-PCR

RNA was extracted from either whole blood or EBV-transformed LCLs. cDNA was prepared from total RNA by the use of Invitrogen SuperScript IV according to manufacturer's instructions with 600 ng input RNA from LCLs and 500 ng input RNA from blood and was primed with an equal mix of anchored dT oligonucleotides and random hexamers unless stated otherwise. A pool of random control cDNAs was prepared and serially diluted to form a relative standard curve against which all samples were quantified. TaqMan probes used were *TYMS* (Hs00426586_m1), *ENOSF1* (Hs01106532_m1), *TFRC* (Hs00951083_m1), *MCM6* (Hs00962418_m1), *TUBA1A* (Hs00362387_m1), and *TP53* (Hs01034249_m1). All reactions were setup with TaqMan Fast Advanced Master Mix according to the manufacturer's instructions. For measuring *TERC* expression, KiCqStart primers (Merck) for *TERC*, *ABL*, *ACTB*, and *GAPDH* were used. The mature *TERC* pool was assessed in RNA extracted from LCLs and blood. In brief, separate cDNA pools were synthesized with anchored dT₍₂₀₎ oligonucleotides and random hexamers from the same sample. The mature *TERC* pools were calculated by comparison of the amounts of amplified *TERC* between these samples. Four replicates per sample were run on the Roche Lightcycler 480 system. All primers had an amplification efficiency between 90% and 100%.

Each gene of interest (GOI) was normalized against the control gene(s), and the relative (n-fold) change between probands and controls was calculated unless stated otherwise.

Isolation of polysome-associated mRNA

This protocol was adapted as previously described²¹ and modified accordingly. In brief, we prepared the cytoplasmic extracts by harvesting proband and control cells in ice-cold PBS containing 100 µg/mL cycloheximide (Sigma). Cells were counted, and 100,000 cells were incubated with 800 µL of RPMI medium containing 10% fetal bovine serum and 100 µg/mL cycloheximide (Sigma) for 5 min at 37°C. After incubation, 200 µL of N-hydroxysuccinimide ester (DSP; 1 mM; Pierce) was introduced as a cross-linking reagent and incubated for 5 min at 37°C followed by quenching with 1 M Tris-HCl (pH 7.4). The cells were washed twice by centrifugation at 1,000 r.p.m. for 3 min and rinsed with ice-cold PBS containing 100 µg/mL cycloheximide (Sigma). The final pellets were swollen for 20 min in 500 µL of low-salt buffer (LSB) (20 mM HEPES [pH 7.4], 100 mM KCl, and 2 mM MgCl₂) containing 1 mM dithiothreitol and lysed by the addition of 500 µL lysis buffer (1× LSB containing 1.2% Triton X-100) (Sigma) followed by brief vortexing. One-tenth (70 µL) of the above lysate was transferred to the Ig-coated beads, and incubation was carried out for 2 h at 4°C. After incubation with the HSP70/HSP73 antibody-conjugated magnetic beads, the polysome complexes containing translationally active mRNA transcripts were isolated and eluted from beads with the Array Pure Nanoscale RNA Purification Kit (Epicentre).

Telomere length measurement

Telomere lengths were measured either by the monochrome multiplex quantitative PCR (MMQPCR) method modified from Cawthon²² or by FLOWFISH as supplied by Repeat Diagnostics.²³ For MMQPCR, in each well the amplified telomeric DNA (T) and a single-copy gene (S) were quantified against a standard curve obtained from the dilution of a reference DNA sample. The T/S ratio, obtained in triplicate for each sample, is directly proportional to the telomere length. This ratio was normalized to the T/S ratio of a second reference sample that was run on every plate to give a relative T/S ratio.

Cellular dNTP analysis

In brief, 10⁶ cells were extracted with 1 mL of ice-cold 60% methanol at 20°C, followed by centrifugation at 16,000 g for 30 min. The supernatant was heat inactivated and vacuum-dried, then rehydrated in 80 mL of water for cellular dNTP measurement by mass spectrometry as described previously.²⁴

Cell-sensitivity assays

Lymphoblastoid cells from affected probands (family 1 II-2; family 2 II-2; and family 3 II-1), parents, and controls were treated with serial doses of either 5-fluorouracil (5-FU) or hydroxyurea dissolved in DMSO at the indicated concentrations. Cell viability was assessed via neutral red-dye uptake by live cells. All chemicals were obtained from Enzo Life Sciences and Sigma Aldrich. All readings were normalized to the untreated sample. We calculated statistical significance by comparing the linear regression of the curves with GraphPad Prism 9 software.

TRAP assay

Cells (10⁵) were lysed in CHAPS buffer for 30 min at a concentration of 3,000 cells/µL. The lysates were centrifuged at 14,000 rpm for 20 min at 4°C. We then diluted 2 µL of eluate in 50 µL of PCR-TRAP reaction and subsequently performed quantification by running the PCR products in non-denaturing 20% TBE gels at 120 V for 30 min and then stained them with SYBR Gold nucleic acid gel stain (Thermo Fischer).

Statistical analysis

Statistical analysis was performed with GraphPad Prism software (version 9), and a p value <0.05 was considered statistically significant. In line graphs, for each experimental dataset, we conducted a linear regression to determine the best-fit line describing the data from each independent experiment. The overall significance of cytotoxicity was determined with a one-way ANOVA and post-hoc Tukey's test on the slopes of the regression lines from each data set (n = 3 independent experiments performed in octuplicate). In scattered dot plots and bar graphs, a Mann-Whitney test was used for determining significant differences in between different cell lines.

Study approval

The affected individuals and families included in this study had all been recruited to the London Dyskeratosis Congenita registry. Blood samples and clinical information were collected at enrolment. All participants and their family members provided written informed consent in accordance with the declaration of Helsinki and the approval of our local research ethics committee (London [city and east] reference number 07/Q0603/5).

Results

Thymidylate synthase (TYMS) deficiency in affected individuals with germline TYMS variants

Recent genome-wide association studies on distinct ethnic human populations have indicated several genes that are important regulators of telomere length.^{25–28} We compiled a list of genes that were common to at least two of these studies and did not include any previously identified telomere-associated genes. We analyzed exomes of 189 DC probands for variants in these genes and identified six previously unreported heterozygous variants in the thymidylate synthase (TYMS [MIM: 188350; GenBank: NM_001071.4]) in affected probands from six independent families (Figure 1A); four of these variants were loss of function (LOF). Targeted sequencing of two additional families who had a strong phenotypic resemblance to the other families revealed that they also had LOF TYMS variants, one of which was seen in a previous family. This series of six LOF variants is a highly significant finding, given that there are only four LOF TYMS variants in the gnomAD database, which comprises more than 125,000 individuals (p < 0.000001: Chi squared with Yates' correction). None of these individuals harboured unique variants in DC or DC-related genes as identified by exome analysis or a targeted gene panel that comprises 111 genes with known associations with bone-marrow failure (Table S2). What was

Figure 1. TYMS deficiency in families affected by dyskeratosis congenita

(A) Pedigrees of proband families are as shown and indicate the presence of the *TYMS* variant in the heterozygous (+/−) state. Black circles and squares denote affected probands.

(B–E) Photographs of affected probands show some of the clinical features: sparse hair, nail dystrophy, abnormal skin pigmentation, and abnormal dentition.

(F) Lymphoblastoid cell lines from the probands and parents show reduced levels of *TYMS* expression compared to that in controls. All genes are normalized to *MCM6* and *TFRC*. Data represent means \pm SD, n = 3, p values determined by one-way ANNOVA. Samples include cell lines from probands (families 1, 2, and 3) and parents (families 1 and 3) and are compared with unrelated controls.

(G and H) Reduced *TYMS* protein amounts in individual proband samples from three families are compared to those in parents and controls; β -actin is used as a loading control.

(I and J) 5-fluorouracil (5-FU) sensitivity demonstrating increased toxicity in lymphoblastoid cells from the probands compared to parents and a control.

also remarkable was that despite the clinical heterogeneity of the genetically uncharacterized DC probands included in our exome series, the *TYMS* families had a consistent phenotype, characterized by an early onset of mucocutaneous features (abnormal skin pigmentation and nail dystrophy) that are the predominant clinical features of classic DC (Figures 1B–E; Table 1). All variants were verified by Sanger sequencing, and they appeared to affect highly conserved amino acid residues in *TYMS* (Figures S1 and S2).

Segregation analysis of all available additional family members (families 1–5 only) showed that one parent who was asymptomatic for the disease also harbored the same *TYMS* exonic variant as their affected offspring, thereby excluding an autosomal-dominant pattern of disease inheritance. Quantitative RT-PCR analysis revealed a highly significant reduction in *TYMS* expression in the lymphoblastoid cells derived from affected pro-

bands of family 1 (II-2), 2 (II-2), and 3 (II-1) when compared to controls (Figure 1F). The *TYMS* expression appears to be similar between the probands and the unaffected parents carrying either the *TYMS* variant ("parent carrier," family 1 I-1; family 3 I-2) or the wild-type variant ("wild-type parent," family 1 I-2; family 3 I-1) (Figure 1F). The reduction of the *TYMS* RNA expression indicates the presence of a second genetic event in the "wild-type parent" cells. However, upon immunoblotting a stark reduction in *TYMS* protein level is observed in the cells of affected probands when compared to the parent carrier, wild-type parent, and the controls (Figures 1G and 1H). Furthermore, cells from the affected probands displayed significant hypersensitivity when exposed to the known specific inhibitor of *TYMS* activity, 5-FU, in comparison to controls and both parents (Figures 1I and 1J). These observations indicate the presence of another genetic variant (or variants)

that could be inherited in an autosomal-recessive fashion from the wild-type parent and that has an impact on the overall TYMS expression.

Altered nucleotide metabolism, impaired telomerase regulation, and genome instability are consequences of TYMS deficiency

TYMS participates in the *de novo* nucleotide synthesis pathway by catalyzing the reductive methylation of deoxyuridine monophosphate (dUMP) to form deoxythymidine monophosphate (dTMP; Figure 2A).²⁹ Analysis of cellular dNTP pool by mass spectrometry revealed an increase in the dUMP nucleotide pools accompanied by a decrease in the dTMP pool as a result of TYMS defi-

ciency affecting the *de novo* pathway for nucleotide synthesis in proband 1's cells (Figures 2B and 2C). We also noticed a substantial increase in the dTTP pool in the proband cells, indicating the activation of the salvage pathway (Figure 2D). Furthermore, a stark increase in thymidine kinase 1 (TK1) amounts correlates with the observation of an increased cellular dTTP pool, whereas a reduction in other key proteins that are involved in initial steps of *de novo* dTMP synthesis is observed in cell lysates of the affected probands (Figure 2E). It has been reported that either the depletion of *de novo* dTMP synthesis or the increase in the cellular dTTP pool, as observed in our affected proband cells, causes genome instability.^{30,31}

Figure 2. TYMS deficiency impacts nucleotide metabolism, telomere maintenance, and genome instability in probands' cells

(A) Schematic diagram showing the proteins involved in different stages (indicated by arrows) of *de novo* and salvage pathways for dTTP synthesis. Abbreviations are as follows: RRM, ribonucleotide reductase catalytic subunits M1 and M2; NDK, nucleoside diphosphate kinase; TYMS, thymidylate synthase; and TK1, thymidine kinase 1.

(B–D) The effect of TYMS deficiency on dNTP pools. Cells from both probands and the control were harvested for analysis of dUMP, dTMP, and dTTP pools. The scattered dot plot represents 1 million cells per dot in each set.

(E) Immunoblotting for key proteins in cell lysates of probands compared with unrelated controls. β -actin is used as a loading control.

(F) Relative telomere lengths of probands are reduced in comparison with those of controls. Age-adjusted T/S ratios analyzed by the MMqPCR method show that probands with TYMS variants have shorter telomere lengths. T/S ratios from probands with either *TERC* or *TINF2* variants are shown for comparison.

(G) Telomere length measurement by flow-FISH in probands from families 1, 4, and 6.

(H) Relative levels of telomerase activity in probands and age-matched control cells at passage 2 were determined by TRAP assay. “IS” indicates internal standard, and * refers to the position of loading dye across the lanes.

(I) Oligo-dT₍₂₀₎-primed mature *TERC* RNA transcripts are distinguished from random hexamer priming of cDNA acquired from RNA samples from lymphoblastoid cell lines of probands (box represents mean and whiskers represent standard deviation).

(J) Immunoblots showing levels of DNA-repair protein at steady state in cells from affected probands and controls. GAPDH is used to determine the loading control.

(K and L) Cell viability in cells from probands, parents, and a control in the presence of hydroxyurea.

(M) Immunoblots showing protein level after hydroxyurea treatment. α -tubulin is used as a loading control.

(N) A representative image of γ H2AX staining in control and index proband cells 24 h after release from hydroxyurea (HU) treatment. Images show DAPI-stained nuclei in blue and γ H2AX in green. The scale bar represents 50 μ m.

Telomere length measurement by qPCR and the flow-FISH method revealed short telomere lengths between the first and tenth centiles (Figures 2F and 2G) in the probands. We also observed that probands' cells grew at a slower rate (Figure S3) and demonstrated reduced levels of telomerase activity (Figure 2H), and this decrease was accompanied by an increase in amounts of oligoadenylated immature *TERC* (Figure 2I). The amounts of DKC1, TERT, and SMUG1, which regulate *TERC* stability, also appear to be reduced (Figure 2J), whereas the amount of shelterin protein components (TIN2, TPP1, TRF1 and POT1; Figure 2J), which protect telomeres, remained un-

changed, indicating that defects in telomere length maintenance are a consequence of impaired telomerase regulation in these TYMS deficient probands as a result of altered nucleotide metabolism.

Furthermore, an increase in the phosphorylation levels of proteins ATM, CHK1, CHK2, p53, p21 in the DNA-damage-response pathway (Figure S4) and hypersensitivity to ribonucleotide reductase inhibitors such as hydroxyurea (Figures 2K–2L) were observed in the cells of TYMS-deficient probands. Time-course release after exposure to hydroxyurea did not sufficiently restore TYMS or RRM1 protein expression and led to further increase of p53

phosphorylation, p21 (Figure 2M) and γ-H2AX (Figure 2N). Collectively, these results suggest that TYMS deficiency alters the cellular dNTP pools and thereby elevates the DNA-damage response and impairs telomerase regulation; both of these effects are considered to be cellular hallmarks of genetically characterized DC-affected probands.^{32,33}

TYMS deficiency occurs via ENOSF1-mediated RNA silencing

The severe TYMS deficiency and the hypersensitivity to both 5-FU and hydroxyurea observed in TYMS-deficient proband cells is clearly distinct from cellular characteristics in the parent carrier and the wild-type parent (Figure 1I–1J and 2K–2L). Moreover, TYMS expression appeared to fluctuate over passages at low levels in the proband cells when compared to control cells (Figure S5A). In-cell RNA cross-linking and affinity capture of translating polysomes via HSP70 antibody revealed reduced binding of TYMS mRNA to actively translating ribosomes in cells from the affected proband (Figures S5B and S5C). These results clearly demonstrate that reduced TYMS translation is occurring by post-transcriptional inhibition of TYMS mRNA binding to translating polysomes in affected proband cells.

ENOSF1 (enolase super family 1 [MIM: 607427]) has been shown to modify TYMS expression at the RNA level by acting as an antisense molecule to TYMS.^{34,35} *ENOSF1* partially overlaps *TYMS* on chromosome 18 and is transcribed in the opposite direction to *TYMS*. 5-FU is a common treatment in cancer-affected individuals, and many reports demonstrate a pharmacogenetic link between several SNPs in the *TYMS-ENOSF1* locus³⁶ and the development of severe hand-foot syndrome.³⁷ These SNPs have reported associations with 5-FU toxicity that results in either the downregulation of *TYMS* or the upregulation of *ENOSF1* expression, or both. On the basis of the observation of 5-FU hypersensitivity in cells from the probands (Figures 1I and 1J), we sequenced this genomic region (chr18: 623000–716000) to screen for any additional germline variants as well as SNPs associated with 5-FU sensitivity.^{38–40} We observed three additional rare intronic *ENOSF1* variants that might affect *ENOSF1* expression and one *TYMSOS* (*TYMS* opposite strand) variant that were all inherited from the wild-type parent, (Figures 3A and 3B, Table S3). Although no report to date has described the effect of *TYMSOS* in modifying *TYMS* expression, the *ENOSF1* transcript has been shown to act as antisense RNA and inhibit *TYMS* expression. Furthermore, we also identified intronic variants in *ENOSF1* and *TYMS* in the affected probands of family 6 and family 8, respectively, where no parental DNA was unavailable (Table S3). It is noteworthy that a common haplotype is shared by all the probands in families 1–5 and that it is inherited from the parent who does not have the disease-specific *TYMS* variant. This “C-A-ins” haplotype (rs699517-rs2790-rs151264360) is associated with both reduced *TYMS* and

increased *ENOSF1* expression as well as with severe hand-foot syndrome.³⁷ This observation of a defined background haplotype in combination with a loss-of-function variant causing severe *TYMS* deficiency has also been reported in an artificial loss of heterozygosity for the *TYMS* allele in a cancer-cell-line model.⁴¹ This might help to explain the resultant cell phenotype hypersensitivity towards 5-FU in our index probands when compared to the parent carrier (Figure 1J). One of the probands (family 5) who carried *TYMS* exonic missense variant (c.480A>T [p.Gln160His]) has shown a severe adverse response to topical 5-FU when undergoing treatment for her squamous carcinoma and melanoma in her leg (Table 1).

We further evaluated *ENOSF1* RNA expression in cells from the probands and their unaffected heterozygous parents along with controls. This revealed a marked increase in the ratio of *ENOSF1* to *TYMS* expression in proband cells when compared to cells from parents and controls (Figure 3C). This increase in *ENOSF1* expression also appears to be high over passages in the proband cells when compared to control cells (Figure S5D). Lentiviral transduction of GFP-tagged *TYMS* cDNA revealed a clear rescue of endogenous *TYMS* expression, which ameliorated the *ENOSF1* antisense effect by outcompeting with ectopically expressed *TYMS* RNA in the proband cells (Figures 4A and 4B). This rescue of endogenous *TYMS* protein appears to be dose dependent and consistent between two other independent transduction experiments in the proband cells (Figures S6A and S6B). We mapped the RNA-RNA interaction region with two different tools, IntaRNA¹⁹ and RactIP,²⁰ and both identified a putative interaction region spanning nucleotides 564–713 in *TYMS* and 4834–4983 in *ENOSF1*, respectively (Figures S6C and S6D). RNA secondary-structure prediction by RNAfold⁴² revealed similar folding conformations between *TYMS* and *ENOSF1* RNA molecules and accurate base pairing as determined by IntaRNA and RactIP (Figure 4C). Furthermore, silencing of *ENOSF1* by RNA interference revealed a clear rescue of endogenous *TYMS* at both the RNA and the protein level in the proband cells (Figure 4D and 4E). This increase of endogenous *TYMS* expression in the cells of the probands in either fashion further revealed a mild or partial but not complete rescue of cell sensitivity to 5-FU (Figure 4F). Thus, our results indicate a digenic epistatic relationship between *TYMS* and *ENOSF1* alleles, where a combination of linked SNPs together with additional rare variants results in increased expression of *ENOSF1* relative to *TYMS*. This leads to post-transcriptional inhibition of *TYMS* translation by *ENOSF1-TYMS* RNA-RNA interaction, causing severe *TYMS* deficiency and features of DC in these affected individuals.

Discussion

In this study we identified a cohort of pediatric DC individuals who have a homogeneous mucocutaneous phenotype

Figure 3. Haplotype analysis and influence of ENOSF1 variants on TYMS expression

(A) Inheritance of common polymorphisms and the variant of interest in the TYMS-ENOSF1 locus in families I-V. The “C-A-ins” haplotype in red highlights the common inherited allele from the wild-type parent. The relative position of the TYMS-specific allele is highlighted in green. na indicates that a sample was not available. A black-filled symbol indicates an affected individual; an open symbol indicates an unaffected individual; and a gray-filled symbol indicates an asymptomatic carrier of the TYMS exonic variant. The unique 28 bp polymorphic 5'-UTR tandem-repeat sequence that is known as the TYMS enhancer region (TSER; rs45445694) and the 6 bp deletion in the 3' UTR (rs151264360) are shown. The TSER with three polymorphic repeats (3R) has greater TYMS expression levels when compared than the two-repeat sequence (2R), and this is further modulated by the presence of SNP G or C (rs285342) within the 2R when 3R is present.

(B) TYMS-ENOSF1 genomic locus depicting polymorphisms (red arrows) and intronic variants identified in ENOSF1 alleles (blue arrows) and the TYMSOS allele (black arrow) in individuals for whom parental samples were available. Exonic TYMS variants (green arrows) are from all probands in this study. An asterisk indicates a recurrent variant.

(C) ENOSF1/TYMS transcript ratio in control and proband cells as well as an unaffected heterozygote parent TYMS carrier as analyzed by qPCR.

and harbour previously unreported LOF, missense, and somewhat rare germline variants in the TYMS locus that overlaps with ENOSF1 (Figure 1 and Figure 3). On the basis of the stark TYMS deficiency we observed in the cells of affected probands, we propose that a combined digenic effect of TYMS and ENOSF1 variants modifies TYMS expression in triggering disease features in these affected individuals. The parents who are carriers of either of these variants (i.e., affecting only the maternal or paternal TYMS-ENOSF1 locus) remain asymptomatic (Table S3). These complex germline variants at the TYMS-ENOSF1 locus introduce an epistatic effect of ENOSF1 in misbalancing the TYMS allele. This epistatic molecular event represents a unique pathogenetic mechanism and provides an important step towards the genetic and molecular understanding of DC.

Previously, a genetic linkage study on a large consanguineous Pakistani family, where affected members manifested clinical features of syndromic ectodermal dysplasia [ECTD (MIM: 616029)], has revealed a linkage

candidate region on chromosome 18p11.32-p11.3, which includes the TYMS-ENOSF1 locus.⁴³ However, further sequencing did not find that this region harbors any homozygous or biallelic variants segregating with the ECTD phenotype observed in this family. Because somatic features (hair, nails, teeth, and skin pigmentation) of ECTD individuals often overlap with DC,¹⁶ it is tempting to speculate that a combination of variants in this linkage region modify the status of TYMS and ENOSF1 expression and cause ECTD- or DC-like features in this family.

The relative increase in the ratio of ENOSF1 to TYMS transcripts in three independent cell lines obtained from our affected probands (Figure 3C) suggests that high ENOSF1 expression reduces TYMS translation by inhibiting TYMS binding to translating ribosomes via an antisense mechanism (Figures S5B and S5C). This result implies that it is the relative levels of these transcripts (high ENOSF1/TYMS ratio), which in turn determines the overall

Figure 4. Post-transcriptional epistatic silencing of *TYMS* by elevated *ENOSF1* in cells of the affected probands

(A) RNA expression of *TYMS* and *ENOSF1* after rescue by a GFP-TYMS lentiviral particle. Expression is relative to the control-GFP in each proband.
(B) Immunoblotting of *TYMS* protein in control and proband cells transduced with lentivirus particles encoding GFP alone and GFP-tagged *TYMS* cDNA.
(C) The RNA secondary structures of both *TYMS* and *ENOSF1* in this RactIP predicted region is modelled with the RNAfold webserver under default parameters. The purple-colored dashed lines indicate base pairing of RNA residues between *TYMS* and *ENOSF1*.
(D) RNA expression of *TYMS* and *ENOSF1* after transduction with lentiviral particles encoding *ENOSF1* shRNA. Expression is relative to the control-GFP shRNA in each proband.
(E) Immunoblotting of *TYMS* protein in control and proband cells transduced with lentivirus particles encoding *ENOSF1* shRNA.
(F) Cellular sensitivity to 5-fluorouracil (5-FU) in control and proband cells after transduction of lentivirus particles encoding *ENOSF1* RNAi. For (A), (D), and (F), each experiment was performed in duplicate and analyzed in triplicate.

TYMS accumulation and the resulting DC phenotype. Specifically, the exonic *TYMS* variant on one parental chromosome leads to the reduction or absence of *TYMS* expression from that allele. Combined with increased expression of *ENOSF1* from the other parental chromosome, this leads to a further reduction from its *cis* *TYMS* locus, resulting in severe *TYMS* deficiency as observed in cells from our affected probands (Figures 1G–1H). The altered *ENOSF1*/*TYMS* ratio could also be the underlying basis of the severe hand-foot syndrome that is observed in a subset of cancer-affected individuals treated with 5-fluorouracil and related cancer drugs.

As a molecular consequence of *TYMS* deficiency in the cells from probands, alteration in the nucleotide metabolism pathway caused an elevated DNA-damage response and induced the p53/p21 axis, affecting the expression of key proteins (DKC1, SMUG1, and TERT) that are involved in telomerase regulation (Figure 2). These molecular events are considered senescence hallmarks that impair stem cell renewal.⁴⁴ In DC and the related inherited bone-marrow failure syndrome Fanconi anaemia, loss of the hematopoiet-

ic stem cell niche is accompanied by activation of the p53/p21 axis, inducing a replicative senescent phenotype.^{45–47} Furthermore, studies on transgenic mouse models of nucleotide deficiency reported that the fine-tuning of nucleotide metabolism pathways is required for resolution of replication stress and overcoming maturation defects of hematopoietic stem and progenitor cells *in vivo*.⁴⁸

Nucleotide-metabolism disorders represent diverse clinical manifestations, including neurological, immunological, hematological, and renal impairments; adverse reactions to 5-FU therapy; and association with malignancies.⁴⁹ Bi-allelic *DYD*, *TK2*, and *TYMP* variants that participate in the *de novo* synthesis pathway have been reported in individuals manifesting the neuro-gastrointestinal and skeletal-muscle aging disorder dihydropyrimidine dehydrogenase deficiency (DYD [MIM: 274270]) and mitochondrial DNA depletion syndrome types 1 and 2 (MTDPS1 and 2 [MIM: 609560; MIM: 603041]).^{50–52}

Recently, bi-allelic *DUT* (deoxyuridine triphosphatase [MIM: 601266]) variants that hydrolyses dUTP to dUMP

in the *de novo* synthesis pathway were reported in individuals with bone-marrow failure associated with diabetes.⁵³ In our exomes, we also identified probands who came from two independent families, had bi-allelic *DUT* variants, and presented with severe pancytopenia and mucocutaneous skin features (Figure S7). The imbalance that occurs in dNTP pools as a result of variants in the aforementioned genes has been shown to affect mitochondrial DNA more adversely than nuclear DNA. In light of the previous observations that TYMS subcellular localization to mammalian mitochondria regulates the *de novo* synthesis pathway for faithful mitochondrial DNA replication,⁵⁴ it is possible that our reported probands with severe TYMS deficiency have some defects in mitochondrial function.

In summary, our study provides evidence that germline variants at the *TYMS-ENOSF1* locus give rise to severe thymidylate synthase deficiency that disrupts the nucleotide metabolism pathway and that this disruption drives molecular features of genome instability and senescence in a homogenous cohort of DC individuals. These observations highlight the influence of nucleotide-metabolism genes in genome stability and demonstrate that digenic germline variants in both *TYMS* and *ENOSF1* can generate disease features of dyskeratosis congenita.

Data and code availability

The published article includes all genomic variants analyzed during this study. The variant data have been submitted to the ClinVar database under accession numbers SCV002540636 and SCV002540642.

Supplemental information

Supplemental information can be found online at <https://doi.org/10.1016/j.ajhg.2022.06.014>.

Acknowledgments

We would like to thank all the affected probands' families for their participation in this study. We acknowledge financial support provided by UKRI/MRC (MR/P018440/1) and Blood Cancer UK (14032). We would like to thank Patrick Shannon and Enrico Colombo for sending the samples from affected individuals.
