ABSTRACT

X-ray polarimetry is a unique way to probe the geometrical configuration of highly magnetized accreting neutron stars (X-ray pulsars). GRO J1008–57 is the first transient X-ray pulsar observed at two different flux levels by the Imaging X-ray Polarimetry Explorer (IXPE) during its outburst in November 2022. We find the polarization properties of GRO J1008–57 to be independent of its luminosity, with the polarization degree varying between nondetection and about 15% over the pulse phase. Fitting the phase-resolved spectro-polarimetric data with the rotating vector model allowed us to estimate the pulsar inclination (130° , which is in good agreement with the orbital inclination), the position angle (75°) of the pulsar spin axis, and the magnetic obliquity ($\sim 74^\circ$). This makes GRO J1008–57 the first confidently identified nearly orthogonal rotator among X-ray pulsars. We discuss our results in the context of the neutron star atmosphere models and theories of the axis alignment of accreting pulsars.

Key words. accretion, accretion disks – magnetic fields – pulsars: individual: GRO J1008–57 – stars: neutron – X-rays: binaries

1. Introduction

The physics of the interaction of astrophysical plasmas with ultrastrong magnetic and radiation fields in the vicinity of neutron stars (NSs) is reflected in the observed properties of accreting X-ray pulsars (XRP); see [Mushtukov & Tsygankov 2022](#), for a recent review). Therefore, the analysis of observational data can, in principle, be used to study the complex interplay of several physical processes defining such interactions. However, the sheer complexity of the problem together with the large uncertainty in the basic geometry of pulsar emission regions have so far limited the potential of X-ray pulsars as laboratories for studying physics under extreme conditions. The situation might change with the launch of the first imaging space X-ray polarimeter, the Imaging X-ray Polarimeter Explorer (IXPE, [Weisskopf et al. 2022](#)), which has opened a new

observational window onto X-ray pulsars and is considered to be a unique tool with which to break several model degeneracies through independent constraints on the geometrical parameters of the system. During the first year of operation in orbit, IXPE observed several XRPs, yielding results that are at surprising variance with pre-launch theoretical predictions ([Doroshenko et al. 2022](#); [Tsygankov et al. 2022](#)). In particular, the emission of XRPs was expected to be strongly polarized (up to 80%; see, e.g., [Meszaros et al. 1988](#); [Caiazzo & Heyl 2021](#); [Becker & Wolff 2022](#)), and a significantly lower polarization degree (PD) was expected to only be theoretically possible at low accretion rates due to the inverse temperature profile in the atmosphere of an accreting NS ([González-Caniulef et al. 2019](#); [Mushtukov et al. 2021](#)). However, it was found that even bright XRPs (with luminosities exceeding 10^{37} erg s⁻¹) show PDs of well below 20%, even in the phase-resolved data ([Doroshenko et al. 2022](#); [Marshall et al. 2022](#); [Tsygankov et al. 2022](#)).

[†] Deceased.

The cause at the basis of this discrepancy is unclear and can be related not only to the physics within the emission region, but also to the potential complexity of the geometry of the emission region itself, and of the accretion flow, which may affect the observed polarization signal. Different sites of the polarized emission in the NS vicinity were discussed by Tsygankov et al. (2022), who proposed, in particular, (i) intrinsic polarization from polar hotspots, (ii) reflection of the emission by the NS surface, (iii) reflection by the accretion curtain, (iv) reflection by the accretion disk, (v) scattering by the stellar wind, and (vi) reflection by the optical companion. Therefore, to exclude the geometrical factor, probing different scenarios of polarization production in the NS atmosphere requires multiple observations of the same source at different mass-accretion rates.

The most obvious candidates for such an observational campaign are transient XRPCs with a Be optical companion (Be/XRPC; see Reig 2011, for a review) that exhibit regular outbursts every orbital cycle due to enhanced accretion rate at around the time of periastron passage. One of the most predictable and best-studied Be/XRPCs is GRO J1008–57 (Kühnel et al. 2013). This object was discovered in 1993 by the BATSE instrument on board the Compton Gamma-Ray Observatory as a transient XRPC with a spin period of 93.587 ± 0.005 s (Stollberg et al. 1993). GRO J1008–57 shows giant Type II and Type I (associated with the periastron passage) outbursts, which are related to the Be type of the optical companion (B1-B2 Ve star; Coe et al. 2007). The typical peak luminosity of the source during the Type I outburst is about 10^{37} erg s⁻¹, with Type II outbursts being several times brighter, reaching $\sim 5 \times 10^{37}$ erg s⁻¹. The distance to GRO J1008–57 was recently updated using the *Gaia* data to 3.6 ± 0.2 kpc (Fortin et al. 2022). The orbital parameters of the binary system are known as well: the orbital period $P_{\text{orb}} = 249.48 \pm 0.04$ d, the projected semi-major axis $a_x \sin i = 530 \pm 60$ lt s, the longitude of periastron $\omega = -26 \pm 8$ deg, and the eccentricity $e = 0.68 \pm 0.02$ (Coe et al. 2007; Kühnel et al. 2013).

The broadband energy spectrum of GRO J1008–57 is known to depend on the source luminosity and exhibits a double-hump structure at the lowest fluxes (Lutovinov et al. 2021), which is typical of low-luminosity XRPCs (see, e.g., Tsygankov et al. 2019b,a). The cyclotron absorption feature at ~ 88 keV in the energy spectrum of the source was first discovered in the CGRO/OSSE data (Shrader et al. 1999) and was later confirmed by Suzaku and *NuSTAR* as the fundamental at $E_{\text{cyc}} = 75\text{--}78$ keV (Yamamoto et al. 2013; Bellm et al. 2014) and by Insight-HXMT at $E_{\text{cyc}} = 90.3$ keV (Ge et al. 2020). This makes GRO J1008–57 an XRPC with one of the strongest confirmed magnetic fields, of around 10^{13} G. Recently, it was shown that even between periastron passages, the NS continues to steadily accrete matter from the recombined accretion disc, which emits at a level of $\sim 10^{34}\text{--}10^{35}$ erg s⁻¹ (Tsygankov et al. 2017a,b).

Here, we present the results of the analysis of GRO J1008–57 observations performed by IXPE during the source periastron passage in two different luminosity states. First, we describe the observations and the data-reduction procedures in Sect. 2. The results are presented in Sect. 3. We then discuss possible sources of the observed polarization and the geometry of the pulsar in Sect. 4, and finally summarize our results and present conclusions in Sect. 5.

2. Data

The IXPE is a NASA mission in partnership with the Italian Space Agency, and was launched on 2021 December 9. It consists of three identical grazing incidence telescopes, providing

imaging polarimetry over the 2–8 keV energy band with a time resolution of the order of 10 μ s. Each telescope comprises an X-ray mirror assembly and a polarization-sensitive detector unit (DU) equipped with a gas-pixel detector (Soffitta et al. 2021; Baldini et al. 2021). A detailed description of the observatory and its performance is given in Weisskopf et al. (2022).

IXPE observed GRO J1008–57 twice during the same Type I outburst over the periods of 2022 Nov. 13–14 and Nov. 18–20 with a total effective exposure of ≈ 85 ks and ≈ 102 ks, respectively. Level 2 data were processed with the IXPEOBSSIM package (Baldini et al. 2022) version 30.2.1¹ using the Calibration database released on 2022 November 17.

Source photons were collected from a circular region with radius R_{src} of 60'' centered on the source position. Following the prescription by Di Marco et al. (2023) for the sources with high count rate ($\gtrsim 2$ cnt s⁻¹), the background has not been subtracted from the data, because it is negligible. For the timing analysis, the photon arrival times were corrected to the Solar System barycenter using the standard barycorr tool from the FTOOLS package, with the effects of binary motion also taken into account using the orbital parameters from Kühnel et al. (2013).

For the spectro-polarimetric analysis, the flux (Stokes parameter I) energy spectra have been binned to have at least 30 counts per energy channel. The same energy binning has also been applied to the spectra of the Stokes parameters Q and U . Taking into account the high number of source counts and low background level, the unweighted approach has been applied. All the spectra were fitted using the XSPEC package version 12.12.1 (Arnaud 1996) and version 12 of the instrument response functions, and applying the χ^2 statistic. The uncertainties are given at the 68.3% confidence level unless stated otherwise.

3. Results

3.1. Timing analysis

The long-term light curve of GRO J1008–57 obtained with the MAXI all-sky monitor (Matsuoka et al. 2009)² is shown in Fig. 1 along with source light curves as observed by IXPE during the two observations, which differ by a factor of ~ 2 in flux. In the low state, the observed luminosity in the 2–8 keV range was about $L_{\text{low}} = 8.6 \times 10^{35}$ erg s⁻¹, while the bright state had $L_{\text{high}} = 1.6 \times 10^{36}$ erg s⁻¹. The source did not exhibit any significant variability within either individual observation, which allowed us to average all the available data. To study the effect of different mass-accretion rates on the polarization properties, the two observations were first analyzed independently.

The high counting statistics allowed us to measure the spin period of the NS with good accuracy, $P_{\text{spin-high}} = 93.133(3)$ s and $P_{\text{spin-low}} = 93.146(4)$ s, in the first and second IXPE observations, respectively (the reported values and uncertainties are estimated using the phase-connection technique following Deeter et al. 1981). The pulsed fraction – defined as $PF = (F_{\text{max}} - F_{\text{min}})/(F_{\text{max}} + F_{\text{min}})$, where F_{max} and F_{min} are the maximum and minimum count rates in the pulse profile constructed using 80 phase bins – was found to be around 60% in both flux states. The resulting pulse profiles in four energy bands are shown in Fig. 2. The pulse profile has a double-peaked

Fig. 1. Light curve of GRO J1008–57 during the November 2022 outburst. Left: long-term light curve in the 4–10 keV energy band obtained by the MAXI all-sky monitor (black points). Blue and red shaded stripes show the time periods of the first and second IXPE observations, respectively. Right: light curves of GRO J1008–57 in the 2–8 keV energy band summed over three modules of IXPE during the first (top) and second (bottom) observation.

Fig. 2. Pulse profile of GRO J1008–57 in different energy bands as seen by IXPE in the bright (left) and low (right) states. Data from the three telescopes were combined. The zero phase was chosen to coincide for both observations using cross-correlation of the profiles.

shape with the first peak gradually disappearing at higher energies, which is peculiar for this source (see, e.g., Naik et al. 2011). We see that the pulse profiles in the two luminosity states agree well, which already indicates a lack of significant changes in the accretion geometry.

3.2. Polarimetric analysis

To understand whether also the polarimetric analysis supports this conclusion, we conducted pulse phase-averaged and phase-resolved analysis of IXPE data for both observations individually. First, we performed the polarimetric analysis of the data using the formalism by Kislat et al. (2015) implemented

in the IXPEOBSSIM package (Baldini et al. 2022) under the pcube algorithm in the xpbins tool. Phase-averaged analysis in the 2–8 keV energy band resulted in low PD values of $4.1 \pm 0.9\%$ and $3.4 \pm 1.1\%$ for the bright and low states, respectively, with corresponding polarization angle (PA, measured from north to east) values of $-3^\circ \pm 6^\circ.4$ and $-9^\circ \pm 9^\circ.2$; that is, the results are consistent within uncertainties. However, we note that, because the PA is expected to be strongly variable over the pulsar spin phase, these phase-averaged results do not contain a significant amount of useful information.

Therefore, as the next step, we performed a phase-resolved polarimetric analysis. For that, we used all the available data in

Fig. 3. Variations of the normalized Stokes parameters q and u with the pulsar phase, averaged over all DUs in the 2–8 keV energy band (beige circles and arrows) for the bright (left) and low (right) states of GRO J1008–57. Each circle corresponds to a specific phase bin, numbered successively following the binning shown in Fig. 4. The circle radius represents the 1σ uncertainty value. The phase-averaged value is shown with a red cross in the corresponding panel.

each observation in the 2–8 keV band binned into 14 phase bins. The number of phase bins was selected to trace the strongly variable PA from one side and to get sufficiently high statistics from another. The results are shown in Figs. 3 and 4. We see that the normalized Stokes parameters $q = Q/I$ and $u = U/I$ are indeed strongly variable over the pulse phase, resulting in a relatively low phase-averaged PD value.

To properly take the energy dispersion and the spectral shape into account, we also conducted a spectro-polarimetric analysis through a joint fit of the I , Q , and U spectra (prepared with the PHA1, PHA1Q, and PHA1U algorithms in the `xpbin` tool) using the XSPEC package (see Strohmayer 2017). Although the broadband spectrum of the source depends on the luminosity, below 10 keV its shape can be described with a simple absorbed power law in a very broad range of luminosities (Tsygankov et al. 2017a). To account for the remaining calibration uncertainties in the IXPE data, as well as possible spectral complexity due to variations of the spectral parameters with phase, we used a more flexible model of a power law with the high-energy exponential rolloff (`cutoffpl` in XSPEC) to model the phase-averaged spectra.

We first applied the model consisting of a rolloff power law modified by the interstellar absorption (`tbabs` in XSPEC with abundances adopted from Wilms et al. 2000) to the phase-averaged data in the bright and low states, separately. The rolloff power-law component was combined with a constant polarization model (energy-independent PD and PA), `polconst` in XSPEC. An additional multiplicative constant `const` was introduced to account for possible discrepancies in absolute effective area calibration of independent DUs; the constant was fixed to unity for DU1, taken as a reference. The final form of the model in XSPEC is `const*tbabs*polconst*cutoffpl`.

As a result, we obtained polarization parameters fully consistent with values obtained from the energy-binned analysis using the `pcube` algorithm. The parameters of the best-fit model are presented in Table 1. The quality of the obtained fits for both observations can be seen from Fig. 5, where the energy spectra

for I , Q , and U Stokes parameters are shown with the corresponding residuals.

To study the energy spectrum and polarization properties of GRO J1008–57 as a function of the spin phase, we performed the phase-resolved spectro-polarimetric analysis using the same 14 phase bins as above. For the spectral fit, we used a simpler continuum model consisting of a power law (`const*tbabs*powerlaw*polconst`) with the cross-calibration constants fixed at the values derived from the phase-averaged analysis (see Table 1). The fit results (the PD and PA values) are presented in Fig. 4.

We see from Fig. 4 that there is no significant difference in the polarization properties of the source during different observations. Therefore, to increase the counting statistics, we combined the data from both observations after the phase alignment using the broadband pulse profiles. After that, we repeated both phase-averaged and phase-resolved spectro-polarimetric analysis applying the same phase binning and spectral model. To take into account the dependence of the spectral shape on the GRO J1008–57 luminosity in the joint fit, we allowed the absorption value N_H , the photon index, and the normalization to vary independently in the two data sets, whereas PD and PA were tied. In the phase-resolved analysis, all these parameters (including N_H) were allowed to vary over the spin phase to reflect possible inhomogeneities in the flow of matter around the NS. An energy-binned (`pcube`) analysis was performed on the combined dataset as well. The obtained results are summarized in Figs. 4 and 6 and Tables 1 and 2.

Modification of the `polconst` polarization component of the best-fit model with `pollin` and `polpow`, which correspond to a linear and a power-law dependence of PD and PA on energy, respectively, did not lead to any significant improvement of the fit quality. Namely, for the phase-averaged data combined over both observations, this modification resulted in $\Delta\chi^2 \sim 1$ for 2 d.o.f. for both `pollin` and `polpow` models. For the phase-resolved data, and for each phase independently, the $\Delta\chi^2$ value did not exceed ~ 5 for 2 d.o.f. with a corresponding F -test

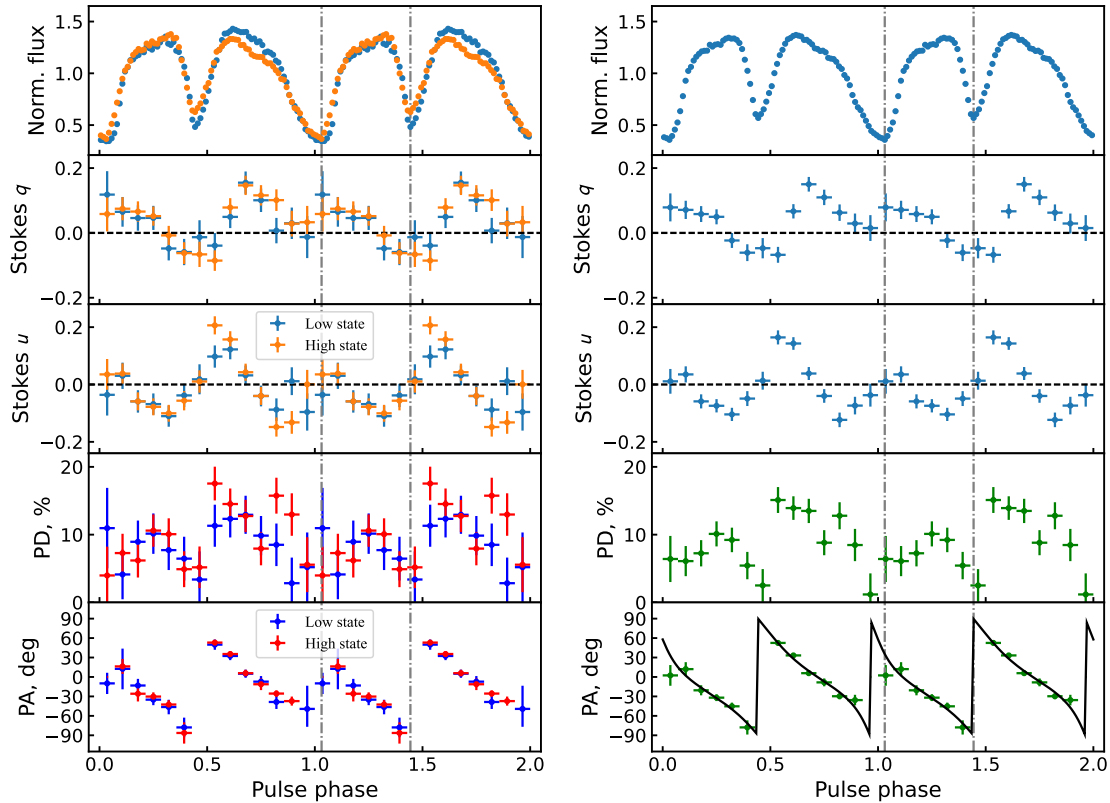

Fig. 4. Dependence of the normalized flux in the 2–8 keV energy band, normalized Stokes parameters q and u (based on the formalism by Kislak et al. 2015), PD, and PA (from the spectro-polarimetric analysis) on the pulse phase for two IXPE observations separately (left) and combined (right). Data from the three IXPE telescopes are combined. Vertical dash-dotted lines show the positions of two minima in the profile and are added for illustrative purposes. The black solid line in the bottom right panel shows the best-fit rotating vector model (see Sect. 4.2).

probability of ~ 0.1 . To increase the counting statistics in order to reveal the energy dependence of PD, we applied the method proposed by Mushtukov et al. (2023). Namely, we simultaneously fitted spectra from all 14 phase bins using the `pollin` model with the PAs frozen at the predictions of the geometrical model discussed in Sect. 4.2. Photon indices were fixed at the values presented in Table 2 and the PD parameters (i.e., normalization at 1 keV, A_1 , and the slope of energy dependence, A_{slope}) were tied for all phases in both observations. As a result, we obtained a phase-averaged PD at 1 keV of $A_1 = 3.5\% \pm 1.8\%$ and a slope of $A_{\text{slope}} = 2.1\% \pm 0.6\% \text{ keV}^{-1}$. The significance of the improvement of the fit with the `pollin` model compared to `polconst` based on the F -test is 2×10^{-4} . This can be considered as a strong indication that the PD of GRO J1008–57 depends on energy. A similar conclusion was recently reached by Forsblom et al. (2023) and Mushtukov et al. (2023) for Vela X-1 and X Persei, respectively.

4. Discussion

4.1. Polarization mechanisms

Under the condition of a strong magnetic field, the medium experiences birefringence when the phase velocity of photons depends on their polarization state. In this case, the photons tend to propagate in the form of two orthogonal polarization modes: the ordinary (O -mode) and extraordinary (X -mode) ones (Gnedin & Pavlov 1974). The polarization of both modes is close to linear. The electric field vector of the X -mode photons oscillates perpendicular to the ambient magnetic field direction,

while the electric vector of O -mode photons has a component along the field. The cross sections of the major processes of interaction between radiation and matter are strongly dependent on the polarization mode (see, e.g., Pavlov & Gnedin 1984; Harding & Lai 2006). Below the cyclotron resonance, the cross sections for photons of the O -mode tend to be significantly larger in comparison to the cross sections of X -mode photons. Consequently, one can expect the flux leaving the NS atmosphere to be dominated by the X -mode photons, resulting in a high PD value; however, this value is also dependent on the specific structure of the atmosphere.

As already mentioned in Sect. 3.2, we did not find any significant difference in the polarization properties of GRO J1008–57 between the two states, with the luminosity differing by a factor of two. We note that the geometry of the emitting regions at the NS surface in XRPs is known to depend on accretion luminosity, and in particular is expected to change dramatically with the onset of an accretion column. Indeed, if the luminosity is below the critical level (Basko & Sunyaev 1976), the radiative force in the vicinity of the NS surface is small and the accretion process results in the emitting regions having a hotspot geometry. If the luminosity reaches the critical value, the radiative force becomes sufficiently high to stop the accreting material above the NS surface in a radiation-dominated shock, resulting in an extended accretion column above the stellar magnetic poles. Taking into account the cyclotron energy observed in GRO J1008–57 at around 80 keV and the corresponding surface magnetic field strength $\sim 10^{13}$ G, one would expect the critical luminosity L_{crit} to be a few times $10^{37} \text{ erg s}^{-1}$ (Mushtukov et al. 2015). This is an order of magnitude higher than the observed luminosity level

Table 1. Spectral parameters for the best-fit model for the two flux states of the source, separately and combined; uncertainties are at 68.3% CL.

Parameter	Value	Units
Bright state		
N_{H}	0.7 ± 0.2	10^{22} cm^{-2}
$\text{const}_{\text{DU}2}$	0.964 ± 0.004

in both observations. We therefore expect the radiative force in the vicinity of the NS surface to have no effect on the dynamics of the accretion flow, and expect the X-ray photons to be emitted from hotspots in both IXPE observations. Therefore, the lack of dramatic changes in the emission region geometry is not surprising.

At subcritical mass-accretion rates, the flow is decelerated in the atmosphere of the NS via Coulomb collisions, resulting in an inverse temperature profile with hotter upper layers and a cooler underlying atmosphere (Zel'dovich & Shakura 1969; Suleimanov et al. 2018). The typical braking distance of the accretion flow in the atmosphere depends on the flow velocity (Nelson et al. 1995), which is similar in the two states of GRO J1008–57, and is not affected by the mass-accretion rate. Therefore, the relative distribution of energy release in the atmosphere is expected to be very similar. The absolute value of the local temperature can be different due to different levels of local energy release. On the other hand, considering that the accretion luminosity in the two observations changes by only a factor ~ 2 , the local temperature is also not expected to change significantly (i.e., by a factor of only $2^{1/4}$). For this reason, we do not expect significant variations in polarization in the two observed states.

Detailed analysis of the radiative transfer problem in the atmosphere of a NS shows that the polarization composition of

X-ray flux leaving the atmosphere is strongly affected by the temperature structure and relative contribution of magnetized vacuum and plasma to the dielectric tensor of the medium. At a certain optical depth in the atmosphere of the NS, the contributions from magnetized vacuum and plasma become comparable, which leads to the mixing of polarization modes, a phenomenon called vacuum resonance. It appears that the optical depth of the vacuum resonance in the atmosphere influences the final contribution of *X*- and *O*-modes to the X-ray energy flux leaving the NS atmosphere. In particular, the low PD observed in both states of GRO J1008–57 can be explained if the position of the vacuum resonance and corresponding mode conversion in the atmosphere is located in the transition region where there are strong temperature and mass density gradients, that is, at the border between the overheated upper layer and colder underlying atmosphere (see details in Doroshenko et al. 2022).

The correlation between the PD and the flux observed during the pulsation period (see Fig. 4) agrees with the expected inverse temperature profile when the accretion luminosity is well below the critical value. Under this condition, the beam pattern of the X-ray radiation emitted at the magnetic poles is suppressed along the normal to the stellar surface (because hotter upper layers contribute more to the flux leaving the atmosphere at a larger angle to the normal), while the PD tends to increase with the angle between the normal and the direction along which the photon leaves the atmosphere because of the stronger dependence of cross sections on X-ray polarization at the larger angles (Mushtukov et al. 2021; Sokolova-Lapa et al. 2021). When the mass-accretion rate is close to the critical one, as in the case of Cen X-3, the beam pattern can already be affected by the scattering of X-ray photons by the accretion flow above the NS magnetic poles, leading to the apparent anti-correlation between the PD and the pulsed flux (see discussion section in Tsygankov et al. 2022).

4.2. Geometry of the system

In order to determine the geometrical parameters of the pulsar, we followed the procedures described in Doroshenko et al. (2022) and Tsygankov et al. (2022). Namely, we fitted the spin-phase variations of the PA of GRO J1008–57 with the rotating-vector model (RVM; Radhakrishnan & Cooke 1969; Poutanen 2020). The applicability of this model – which assumes the dipole configuration of the NS magnetic field – to XRPCs, where the magnetic field near the star can be more complicated, has been discussed in several papers (e.g., González-Caniulef et al. 2023; Taverna et al. 2022). Specifically, the applicability is justified by the birefringence properties of vacuum (Gnedin et al. 1978) causing the radiation propagation in two normal modes until the polarization-limiting radius (Budden 1952; Heyl & Shaviv 2002; Heyl & Caiazzo 2018). For a typical XRPC, this radius is about 20 stellar radii ($\sim 250 \text{ km}$), which is much larger than the star and therefore we expect the field configuration there to be dipolar.

If radiation escapes in the *O*-mode, the PA can be described by the RVM, following the expression (Poutanen 2020)

$$\tan(\text{PA} - \chi_{\text{p}}) = \frac{-\sin \theta \sin(\phi - \phi_0)}{\sin i_{\text{p}} \cos \theta - \cos i_{\text{p}} \sin \theta \cos(\phi - \phi_0)}, \quad (1)$$

where i_{p} is the pulsar inclination (i.e., the angle between the pulsar spin vector and the line-of-sight), χ_{p} is the position angle of the pulsar spin axis, θ is the magnetic obliquity (i.e., the angle between the magnetic dipole and the spin axes), ϕ is the pulse

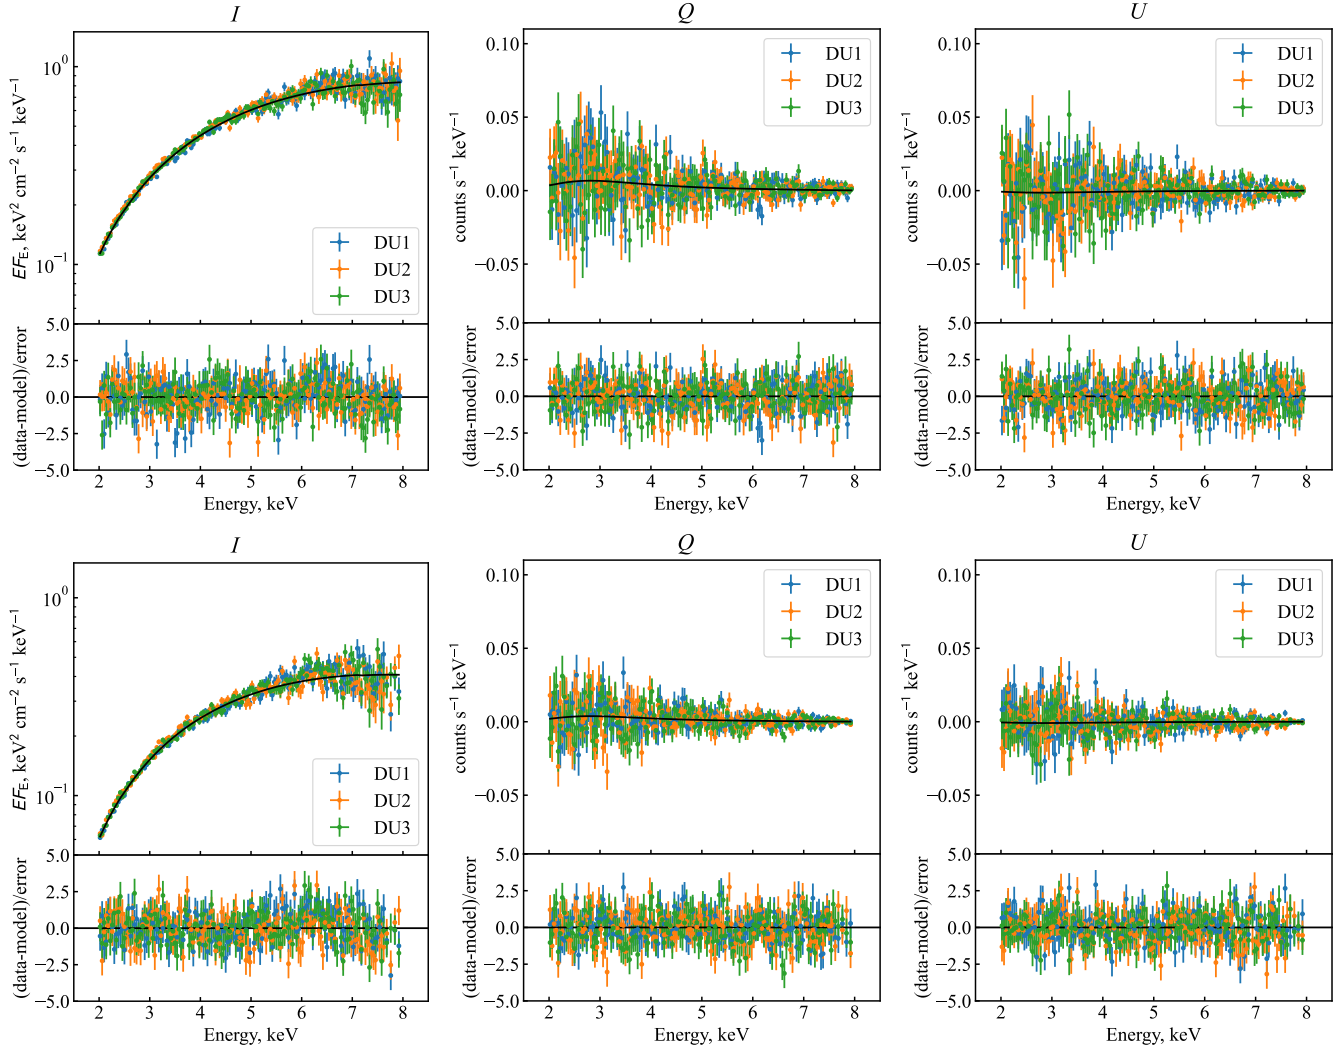

Fig. 5. Energy distributions of the Stokes parameters I , Q , and U for the bright (upper plots) and low (lower plots) states of GRO J1008–57 with the best-fit model shown with the black solid line. The residuals between the data and the model normalized for the errors are shown in the bottom panels of the corresponding plots. The different colors represent the three IXPE detectors: DU1 in blue, DU2 in orange, and DU3 in green.

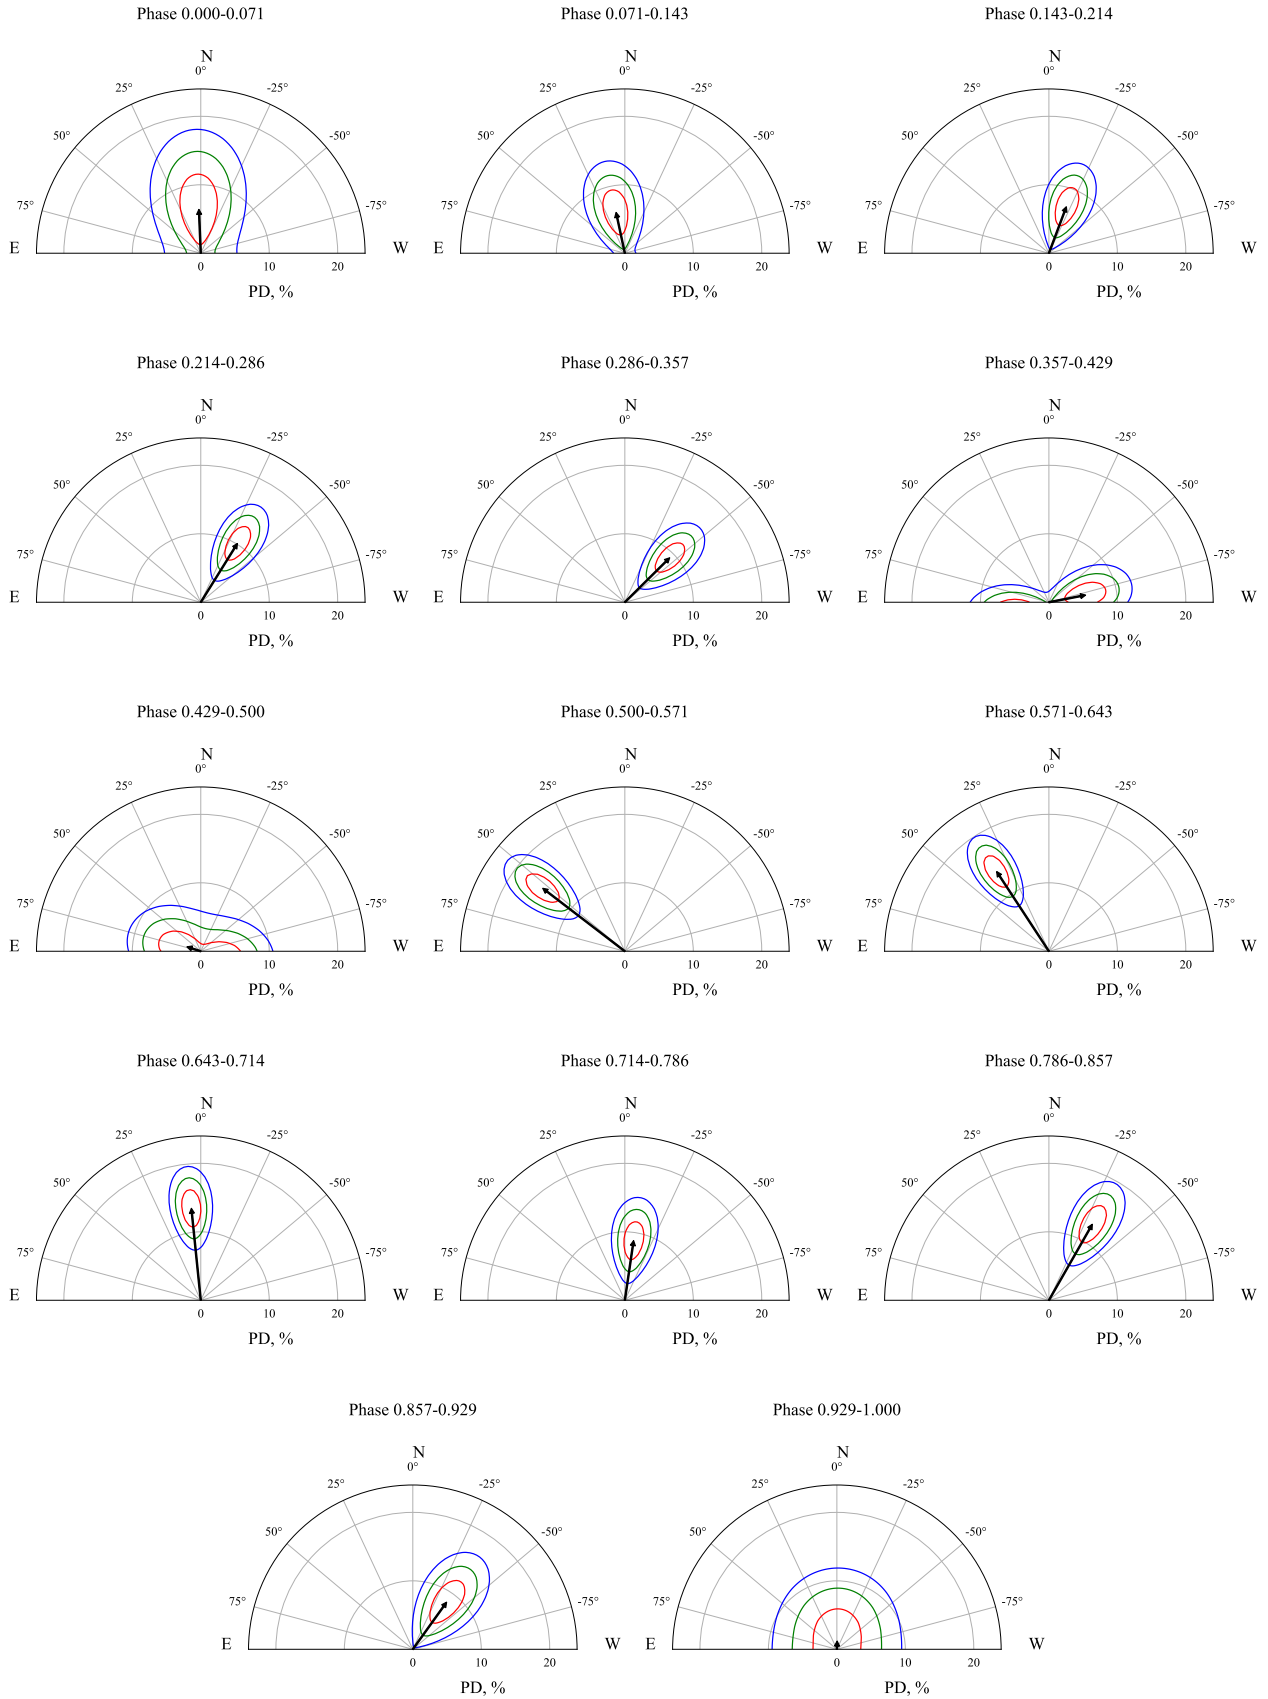

Fig. 6. Polarization vectors as a function of the phase of GRO J1008–57 based on the spectral fitting of the combined data from both IXPE observations. In each plot, the PD and PA contours at 68.27%, 95.45%, and 99.73% confidence levels (red, green and blue, respectively) are shown in polar coordinates for 14 different phase intervals (coinciding with the ones defined in Fig. 4).

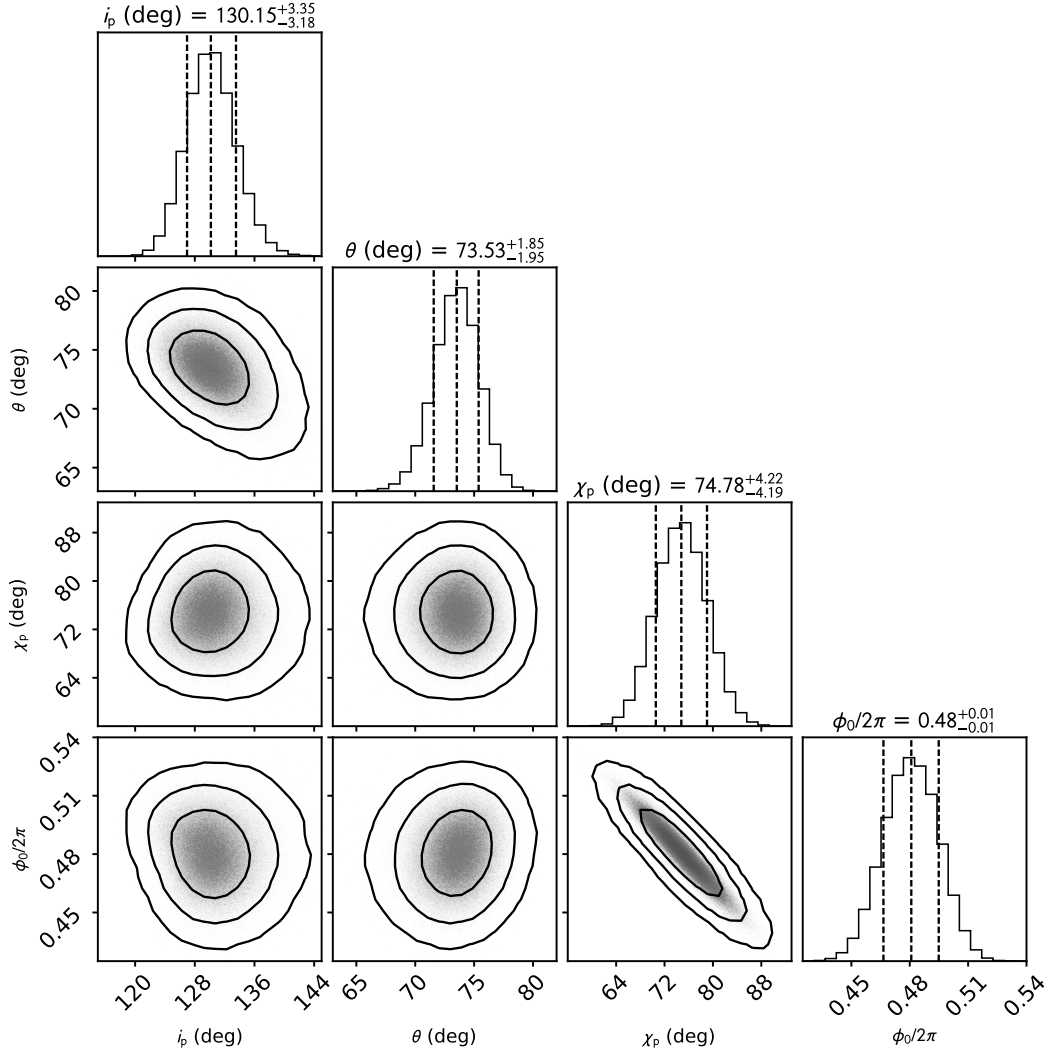

Fig. 7. Corner plot of the posterior distribution for the RVM parameters for the pulsar geometry obtained using the PA values from the phase-resolved spectro-polarimetric analysis of the combined data. The two-dimensional contours correspond to 68.27%, 95.45%, and 99.73% confidence levels. The histograms show the normalized one-dimensional distribution for each parameter derived from the posterior samples. The mean value and 1σ confidence interval for the derived parameters are presented above the corresponding histogram (dashed lines).

phase, and ϕ_0 is the phase when the magnetic pole is closest to the observer.

The pulse-phase dependence of the PA obtained from the spectro-polarimetric analysis of the combined data was fitted with the RVM using the affine invariant Markov chain Monte Carlo ensemble sampler EMCEE package of PYTHON (Foreman-Mackey et al. 2013). All the parameters in Eq. (1) were left free. As a result, we obtained accurate estimates of the pulsar inclination, $i_p = 130^{\circ}2 \pm 3^{\circ}3$, the co-latitude of the magnetic pole, $\theta = 73^{\circ}5 \pm 1^{\circ}9$, and the position angle of the pulsar spin, $\chi_p = \chi_{p,o} = 74^{\circ}8 \pm 4^{\circ}2$ (see Figs. 4 and 7). However, the pulsar spin-axis position angle is not determined uniquely and can be directed in the opposite direction at $\chi_p = \chi_{p,o} + 180^{\circ} = 254^{\circ}8 \pm 4^{\circ}2$ because only the orientation of the polarization plane can be measured. Also, if radiation escapes in the X-mode, then the pulsar spin is oriented at $\chi_p = \chi_{p,x} = \chi_{p,o} \pm 90^{\circ}$. The obtained geometrical parameters were verified using the RVM fit to the unbinned Stokes parameters on a photon-by-photon basis as outlined in González-Caniulef et al. (2023) and Marshall (2021). We find that the PD and PA obtained in this way is nearly identical to those shown in Fig. 4.

Furthermore, the inclination of the pulsar estimated from IXPE data ($i_p \approx 130^{\circ}$) appears to be close to the orbital inclination of $\sim 144^{\circ}$ estimated by Coe et al. (2007) based on an analysis of the H α emission line profile from a circumbinary Be disk³. Although the accuracy of the latter estimate might be debated, it indicates that the accretion torques had sufficient time to align the spin and orbital axes. Very rough estimates result in alignment timescales of the order of $\lesssim 10^5$ yr for a NS with a strong magnetic field (see Eq. (16) in Biryukov & Abolmasov 2021).

It is interesting to note that the resulting determination of the co-latitude of the magnetic pole points to a very high value of $\theta \approx 75^{\circ}$, which tells us that GRO J1008–57 is an almost orthogonal rotator. This finding is in stark contrast with results for Cen X-3 and Her X-1, where the magnetic obliquity was much lower, at about 16° (Doroshenko et al. 2022; Tsygankov et al. 2022). Observations of other XRPCs with IXPE, that is, Vela X-1 (Forsblom et al. 2023) and X Persei (Mushtukov et al. 2023), also imply either low or high values of magnetic obliquity. These results are in fact in line with some studies predicting a bimodal

³ The actual value of inclination reported by Coe et al. (2007) is $\sim 36^{\circ}$, but this cannot be distinguished from $180^{\circ} - 36^{\circ} = 144^{\circ}$.

distribution of the magnetic obliquity θ peaking around 0 and 90 deg in the case of isolated NSs (e.g., Lander & Jones 2018). However, we note that in the case of accreting NSs, the predictions are less specific depending on the accretion mechanism (Biryukov & Abolmasov 2021). More observations of XRP with IXPE will allow us to verify models of the axis alignment of accreting pulsars.

5. Summary

The results of our study can be summarized as follows:

1. GRO J1008–57 was observed by IXPE during the Type I outburst in November 2022 in two states, which differ in flux level by a factor of 2.
2. Both the energy-binned and spectro-polarimetric analyses of the phase-averaged data reveal a significant average polarization of the source with a PD of $\sim 3.9\%$ regardless of the source flux.
3. The pulse-phase resolved analysis reveals a correlation between the flux and the PD, and suggests that a strong variation of the PA is responsible for the low average polarization from the source. The results obtained in the two luminosity states are consistent within the uncertainties. We also find an indication that the PD is positively correlated with energy.
4. The observed variations of the PA are well described in the framework of the rotating-vector model. The corresponding inclination of the pulsar is about 130° , and the position angle of the pulsar spin is $\sim 75^\circ$ (or 255°) if radiation escapes from the surface in the O-mode, or $\sim 165^\circ$ (or -15°) if the X-mode dominates. In all cases, the magnetic obliquity is found to be very large $\sim 75^\circ$, implying that GRO J1008–57 is a nearly orthogonal rotator.
5. The observed pulsar inclination appears to agree with the estimated orbital inclination of the system, suggesting that the pulsar spin is close to being aligned with the orbital axis. This indicates that, in spite of a strong natal kick received by the NS, the accretion torques (even though acting sporadically) had sufficient time to align the spin and orbital angular momenta.
6. The relatively low polarization detected from GRO J1008–57 as well as the finding that the polarization properties are independent of the mass accretion rate can be explained in the framework of the model of an overheated NS atmosphere.

Detecting changes in the polarization properties with mass accretion rate requires observations of an XRP during giant Type II outburst. Such observations were performed by IXPE in February 2023 for the Be/XRP LS V +44 17/RX J0440.9+4431, where strong variations of the PD and PA in different luminosity states were discovered (Doroshenko et al. 2023).
