Prediction of atrial and ventricular arrhythmias using multiple cardiovascular risk-factor polygenic risk scores @

Julia Ramírez, PhD,<sup>1,2,3</sup> Stefan van Duijvenboden, PhD,<sup>3,4,5</sup> Michele Orini, PhD,<sup>5,6</sup> Pier D. Lambiase, MD, PhD, FHRS,<sup>5,7</sup> Andrew Tinker, MB, BS, PhD,<sup>3,8</sup> William J. Young, PhD,<sup>3,7</sup> Patricia B. Munroe, PhD<sup>3,8</sup>

#### **ABSTRACT**

**BACKGROUND** Atrial fibrillation (AF) prediction improves by combining clinical scores with a polygenic risk score (PRS) for AF (AF-PRS), but there are limited studies of PRS for ventricular arrhythmia (VA) prediction.

**OBJECTIVE** We assessed the value of including multiple PRS for cardiovascular risk factors (CV-PRS) for incident AF and VA prediction.

**METHODS** We used 158,733 individuals of European ancestry from UK Biobank to build 3 models for AF: CHARGE-AF (AF1), AF1 + AF-PRS (AF2), AF2 + CV-PRS (AF3). Models for VA included sex and age (VA1), VA1 + coronary artery disease (CAD) PRS (CAD-PRS, VA2), and VA2 + CV-PRS (VA3), conducting separate analyses in subjects with and without ischemic heart disease (IHD). Performance was evaluated in individuals of European (N = 158,733), African (N = 7200), South Asian (N = 9241) and East Asian (N = 2076) ancestry from UK Biobank.

**RESULTS** AF2 had a higher C-index than AF1 (0.762 vs 0.746, P < .001), marginally improving to 0.765 for AF3 (P < .001, including PRS for heart failure, electrocardiogram and cardiac magnetic resonance measures). In South Asians, AF2 C-index was higher than AF1 (P < .001). For VA, the C-index for VA2 was greater than VA1 (0.692 vs 0.681, P < .001) in Europeans, which was also observed in South Asians (P < .001). VA3 improved prediction of VA in individuals with IHD.

**CONCLUSION** CV-PRS improved AF prediction compared to CHARGE-AF and AF-PRS. A CAD-PRS improved VA prediction, while CV-PRS contributed in IHD. AF- and CAD-PRS were transferable to individuals of South Asian ancestry. Our results inform of the use of CV-PRS for personalized screening.

#### Introduction

Atrial and ventricular arrhythmia are a cause of substantial morbidity and mortality in the general population. Atrial fibrillation (AF) is the most common cardiac arrhythmia and associated with increased risk for cardioembolic stroke and heart failure (HF). Ventricular arrhythmia (VA) are the primary cause of sudden cardiac death, with  $\sim 50\%$  of these deaths occurring in individuals considered low risk using current clinical

criteria.<sup>2</sup> Therefore, AF and VA risk stratification tools need to improve the identification of high-risk individuals in low-risk populations who may benefit from early implementation of primary prevention strategies.

The Cohorts for Heart and Aging Research in Genetic Epidemiology (CHARGE)-AF score was developed for primary screening of incident AF risk in the general population.<sup>3</sup> A polygenic risk score (PRS) combining an individual's genetic

predisposition for AF showed a strong association with AF risk independently from traditional risk factors. When combined with the CHARGE-AF score, 3 times as many AF cases were identified compared with CHARGE-AF alone. For VA, there is no established clinical score, but male sex and age are the main risk factors in the general population. Arecent study has reported a coronary artery disease (CAD) PRS is associated with sudden cardiac death in patients with CAD and cardiovascular comorbidities independently from sex and age, with a 70% improvement in discrimination when combined

with clinical risk factors.

IHD: ischemic heart disease

MRI: magnetic resonance image

PRS: polygenic risk score

VA: ventricular arrhythmia

tors is still unknown, although this investigation would inform on their utility in risk stratifying individuals who are otherwise healthy, in which there are potentially few confounding factors.

We thus hypothesized that additional PRS for AE and VA

We, thus, hypothesized that additional PRS for AF and VA cardiovascular risk factors, including ECG and MRI risk markers in combination with clinical scores, may capture additional electrophysiological mechanisms relevant for risk stratification. We have tested this in a middle-aged population of European ancestry without prevalent cardiovascular disease at recruitment (Figure 1), as well as in individuals with African, South Asian, and East Asian ancestry. We also performed sexstratified analyses and repeated incident VA association analyses in individuals with and without prevalent ischemic heart disease (IHD).

# **Methods**

## Study population

UK Biobank is a prospective study of 502,505 individuals, aged 40 to 69 years old at recruitment (2006–2008). UK Biobank has approval from the North West Multi-Centre Research Ethics Committee, and all participants provided informed consent. The research reported in this paper adhered to the Helsinki Declaration as revised in 2013. For AF and VA, individuals with a diagnosis of CAD, VA, AF or heart failure at recruitment were excluded using international Classification of Diseases, Tenth Revision (ICD-10) codes (Supplemental Table S1). The main analysis included 398,716 unrelated individuals of

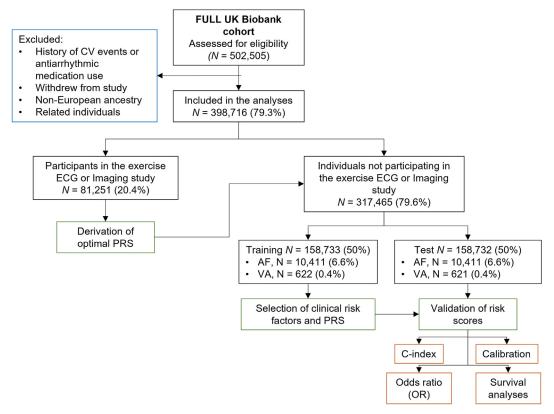

Figure 2
Flowchart indicating the number of individuals included in the study and the partition into training and test for incident atrial fibrillation (AF) and ventricular arrhythmia (VA) risk prediction. CV = cardiovascular.

European-ancestry (Figure 2). A subset of 81,251 individuals who participated in the UK Biobank exercise stress test or in the imaging study was used to obtain the list of variants and weights to build the optimal PRS for each cardiovascular risk factor trait. The remaining 317,465 independent individuals were further split into training (50%) and test (50%) subsets. The training subset was used to derive specific models associated with incident AF and VA, and their performance was evaluated in the test subset (Figure 2). Models were additionally tested in unrelated individuals without prevalent CAD, VA, AF, or HF of African (N = 7200), South Asian (N = 9241) and East Asian (N = 2076) ancestry from UK Biobank, given their different genetic background.

### AF and VA risk definition

The primary endpoints of the study were incident AF and VA as recorded in hospital episode statistics using ICD10 codes I48, I480, I481, I482, and I489 for AF and I460, I461, I472, and I490 for VA. Follow-up was from the study inclusion date until November, 2022 (median of 13.6 years, interquartile range of 1.2 years).

# Calculation of polygenic risk scores

Selection of each PRS was based on a previous electrophysiological hypothesis for their association with risk of AF or VA. In total, 36 PRS for clinical risk factors and ECG and MRI

measures were derived (Supplementary Methods, Table 1). All PRS were standardized by subtracting the mean and dividing by their standard deviation so that their effect sizes in the models were comparable.

#### Training of statistical models

In the training set, we fitted 3 models: CHARGE-AF (AF1), CHARGE-AF and the AF PRS (AF2), 4 and AF2 and the other 35 PRS (AF3). The CHARGE-AF score was calculated using the original model originally described. 3 Models 2 and 3 were also adjusted for the genetic array and the first 10 principal components. 26 PRS were included as continuous variables in the models.

For each model, we performed univariable logistic regression analyses to determine the relationship between each risk factor and incident AF risk. Then, we took forward into multivariable logistic regression models, clinical risk factors or PRS that were significantly associated with AF (P<.05) using backward stepwise elimination to remove markers with a nonsignificant association with the Akaike information criterion ("stepAIC" function from the "MASS" package in R [R Foundation for Statistical Computing, Vienna, Austria]).

We followed a similar approach for the prediction of VA risk, also fitting 3 models: sex and age (VA1), sex, age and a CAD PRS<sup>4</sup> (VA2), and sex, age, a CAD PRS and the other 35 PRS (VA3).

AF = atrial fibrillation; BMI = body mass index; CAD = coronary artery disease; DBP = diastolic blood pressure; DCM = dilated cardiomyopathy; GWAS = Genome-wide Association Study; HCM = hypertrophic cardiomyopathy; HDL = high-density lipoprotein; HR = heart rate; LAAEF = left atrial active emptying fraction; LAmin = left atrial minimum volume; LDL = low-density lipoprotein; LVEDV = left ventricular end-diastolic volume; LVEF = left ventricular ejection fraction; LVESV = left ventricular end-diastolic volume; LVM = left ventricular end-diastolic volume; RVEDV = right ventricular end-diastolic volume; RVESV = right ventricular end-diastolic volume; PP = pulse pressure; SBP = systolic blood pressure; SNV = single nucleotide variant; TMR = T-wave morphology restitution.

#### Test of statistical models

In the independent test subset (Figure 2), we calculated risk scores as the weighted sum of significant clinical risk factors and PRS in the respective multivariable models from the training set, weighted by the corresponding beta coefficients.<sup>26,27</sup>

Performance of the risk scores was evaluated by measuring the concordance index (C-index). We used bootstrapping to calculate a population of C-indices and to extract (Cls) intervals. Then, the likelihood ratio test (LRT, package "Imtest" in R) was used to compare nested models. Calibration of the models was evaluated using the integrated calibration index and the scaled Brier score ("psfmi" library in R); calibration plots were made using the "predtools" library in R The net reclassification improvement (NRI) was computed using the package "PredictABEL" in R to quantify the added predictive value of each score beyond that from the corresponding preceding one for both AF and VA risk. The risk categories used for the NRI analysis were equivalent to the event rate for each endpoint.

Next, for each score and endpoint, we identified 2 risk groups based on their training-specific optimal cutoff, calculated as the value of the score that jointly maximized both sensitivity and specificity values using the "cutpointr" package in R. Thus, risk groups were defined as low risk (test score values < optimal cutoff) and high-risk (test score values > optimal cutoff). Odds ratios (ORs) were calculated using the low-risk group as a reference. To evaluate the dependency of the results on the choice of threshold, we repeated the low- and high-risk split using the cutoff value that marks the 90th percentile of the scores in the training set.

Finally, we performed survival analyses; Kaplan-Meier curves were derived using the optimal cutoff values, with a comparison of cumulative events performed by using log-rank tests, and plotted using the "survminer" package in R. Hazard ratios (HRs) were derived taking the low-risk group as a reference using univariable Cox regression analyses.

Table 2 Characteristics of the cohort							
	All	Training	Test				
Risk factor or endpoint	N = 317,465	N = 158,733	N = 158,732	P

#### Sex-stratified analyses

To investigate sex-specific contributions of the multiple PRS for incident AF and VA risk stratification, we performed sex-stratified analyses by repeating the training and testing of statistical models in men and women separately.

# Incident VA prediction in individuals with and without IHD

Finally, we performed separate incident VA association analyses by repeating the training and testing of statistical models in individuals with and without prevalent IHD to determine whether the underlying aetiology of VA affects PRS performance (Supplemental Methods, Supplemental Figures S1 and S2).

#### Performance assessment in non-European ancestries

To assess the generalizability and performance of the statistical models trained in the European individuals for non-European ancestry individuals, we tested in individuals with African, South Asian, and East Asian ancestry. To reduce the variation in the PRS distribution due to genetic ancestry, we used the residuals from a linear model after regressing each PRS on the first 4 genetic PCs, as previously described.<sup>28</sup>

#### **Results**

The study population consisted of 138,929 men, with a median (interquartile range) age of 58 (13) years old. The demographic characteristics of this population are shown in Table 2.

#### Prediction of incident AF

During the follow-up period, there were 10,411 AF cases (6.6%) in each of the training and test sets (Figure 2). The C-index for AF1 (CHARGE-AF) was 0.746 (0.742-0.751) in the test set, which significantly increased to 0.762 (0.757-0.766,  $P < 2.2 \times 10^{-16}$ ) when using AF2 (CHARGE-AF + AF PRS, Figure 3). The C-index for AF3 was statistically significantly higher than that for AF2 (0.765 [0.760-0.769], P < 2.2  $\times$  10<sup>-16</sup>. The PRS for HF, T-wave morphology restitution (TMR) after exercise, body mass index (BMI), QT dynamics during exercise, left ventricular ejection fraction (LVEF), T-peak to T-end (T-pe) interval, resting heart rate, left ventricular ejection systolic volume (LVESV), left atrial active minimum volume (LAmin), Brugada syndrome, QRS duration and QT interval (in decreasing order of magnitude and direction of effect) remained significantly associated with incident AF in AF3 (Figure 3). The overall mean NRI was 0.288 (0.268-0.308, P < .001) for AF2 vs AF1, and 0.110 (0.090-0.001)0.130, P < .001) for AF3 vs AF2 (Supplemental Tables S2 and S3). Calibration metrics and overall performance of each model using the "optimal" and the 90th percentile thresholds are shown in Supplemental Table S4 and Supplemental Figure S3). Finally, OR values and 95% CI for individuals in the high-risk group vs those in the low-risk group progressively increased from 4.85 (4.63-5.08) for AF1, to 5.24 (5.01-5.48) for AF2, and 5.56 (5.31-5.83) for AF3 (Figure 3). HR values increased from 4.83 for AF1, to 5.17 for AF2 and to 5.49 for AF3 (Figure 4).

In sex-specific analyses, AF2 had a significantly higher C-index than AF1 in both men (N = 69,432 in the test set,

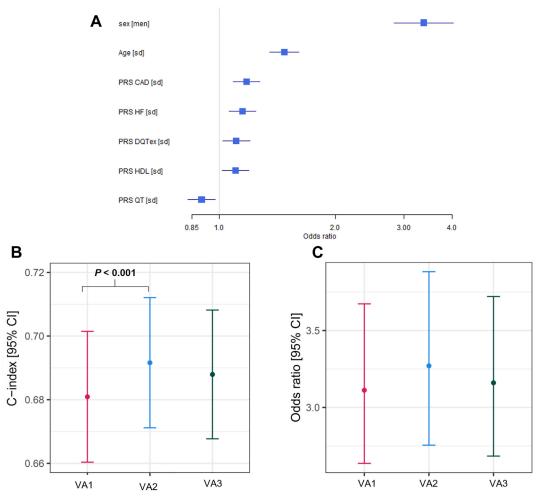

Figure 5
Prediction of incident VA risk. A: Forest plot illustrating the odds ratio of sex, age, the CAD PRS and each PRS for cardiovascular risk factors and ECG or MRI risk markers that remained significant in the adjusted model. Concordance indices and odds ratios obtained for sex and age score (magenta), sex, age and the CAD PRS (cyan) and sex, age, the CAD PRS and the PRS depicted in panel (A) (green) for incident VA risk prediction are shown in (B) and (C). CAD = coronary artery disease. Other abbreviations as in Figure 3.

6151 AF cases) and women (N = 89,300 in the test set, N = 4260 AF events). In men, AF2 showed an NRI of 0.287, and OR and HR values for AF1 and AF2 of 4.05 and 4.55, and 4.04 and 4.48, respectively. In women, NRI was 0.284, and OR and HR values were 5.36 for AF2 vs 4.86 for AF1, and 5.30 for AF2 vs 4.85 for AF1 (Supplemental Figures S3, S4, and S5, Supplemental Tables S5, S6, and S7). However, cardiovascular (CV)-PRS (the same PRS from the main analysis, except for the PRS for TMR after exercise, QT dynamics during exercise, LVEF, T-pe interval, and LAmin and the addition of CAD and the PR interval) only showed a significant contribution in men. These jointly increased the C-index to 0.772 ( $P = 4.6 \times 10^{-4}$ ) and the OR to 4.51, with an NRI of 0.121 (0.094–0.147, P < .001, Supplemental Figure S4, Supplemental Table S7).

We tested the performance of each model trained in the main analysis in individuals with African (166 AF cases), South Asian (275 AF cases) and East Asian (42 AF cases) ancestry. In individuals of South Asian ancestry, AF2 had a significantly higher C-index than AF1 (0.787 [0.760–0.813] vs 0.774

[0.746–0.802],  $P=2.9\times10^{-5}$ ), which significantly increased to 0.791 (0.764–0.817),  $P=1.8\times10^{-4}$ , for model AF3 (Supplemental Table S4, Supplemental Figure S6). The ORs were 6.52 (4.87–8.72) for AF1, 7.08 (5.31–9.45) for AF2, and 7.59 (5.64–10.22) for AF3, and the HR values were 6.61, 7.16, and 7.64, respectively. In individuals with African or East Asian ancestry, AF2 or AF3 did not significantly improve the predictive value already provided by CHARGE-AF in AF1 alone; however, there were a smaller number of cases in these ancestry groups.

#### Prediction of incident VA risk

For prediction of incident VA, there were 621 and 622 VA cases (0.4%) in the training and test sets, respectively (Figure 2). VA1 (sex and age) showed a C-index of 0.681 (0.660–0.701), which significantly increased for VA2 (sex, age and a CAD PRS, 0.692 [0.671–0.712],  $P=4.1\times10^{-11}$ , Figure 4). NRI was 0.314 (0.236–0.392, P<.001, Supplemental Table S8), calibration and performance metrics

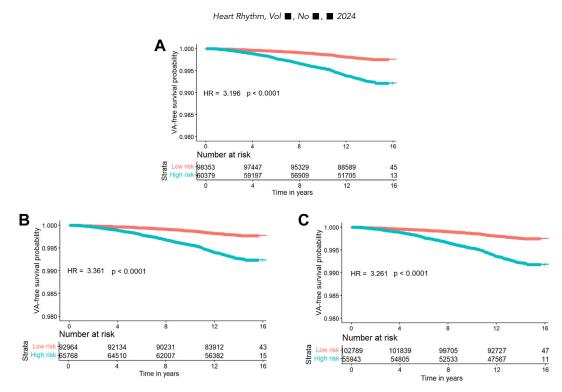

Figure 6
Cumulative ventricular arrhythmia-free survival probability of individuals in the low- (red) and high-risk (blue) groups for models VA1 (A), VA2 (B), and VA3 (C). HR = hazard ratio.

are shown in Supplemental Table S9 and Supplemental Figure S7). OR and HR values were 3.11 (2.64–3.67) and 3.27 (2.76–3.88), and 3.20 and 3.36, respectively (Figures 5 and 6). After fitting model VA3, the PRS for HF, QT dynamics during exercise, HDL and QT interval remained significantly associated with incident VA, independently from sex, age, and the CAD PRS. However, in combination, they did not improve discrimination compared with VA2 (Figure 5). HR values were 3.20 for VA1, 3.36 for VA2, and 3.26 for VA3 (Figure 6).

Sex-specific analyses (69,465 men in the training set, 441 VA cases, and 69,464 men in the test set, 441 VA cases) showed similar findings, with VA2 having a significantly higher performance than VA1, but the contribution of CV-PRS not being statistically significant (Supplemental Figures S8 and S9, Supplemental Tables S10 and S11).

There were 561 VA cases (5%) in both the training and test sets in individuals with prevalent IHD. Age was not significantly associated with incident VA, and sex alone had a C-index of 0.545 (0.528–0.563). The CAD PRS was not significantly associated with incident VA. Thus, VA3 included sex and the PRS for diastolic blood pressure (DBP) and dilated cardiomyopathy (DCM) (the 2 PRS that remained significantly associated in model VA3). There was a significant increase in the C-index to 0.592 (0.560–0.624,  $P=8.5\times10^{-3}$ ) with a mean NRI of 0.216 (0.0972–0.3352, P=0.004, Supplemental Tables S9 and S12, Supplemental Figure S10). OR and HR values were 1.86 (1.44–2.42) and 1.84 (Supplemental Figure S11). In individuals without IHD, there were 653 VA cases (0.2%) in both training and test subsets. The C-index

was 0.654 (0.625–0.684) for VA1, and the OR was 3.01 (2.41–3.75). However, the addition of the CAD PRS (VA2), or VA3 (here the PRS for HF and the spatial QRST angle were the only 2 PRS that remained significantly associated with incident VA), did not significantly improve model performance (Supplemental Table S12).

We finally tested the performance of each model trained in the main analysis in individuals of African, South Asian and East Asian ancestries. We observed that, in individuals with South Asian ancestry (46 VA cases), VA2 had a significantly higher C-index than VA1 (0.722 [0.648–0.796] vs 0.640 [0.579–0.700],  $P=3.2\times10^{-4}$ ). However, the C-index of VA3 was not significantly higher than that of score 2 ( $P=1.7\times10^{-1}$ , Supplemental Table S9, Supplemental Figure S12). The OR and HR values were 3.56 (1.76–7.17) and 4.10 for VA1, 2.41 (1.30–4.47) and 4.3 for VA2, and 2.26 (1.26–4.08) and 5.60 for VA3. In individuals with African (22 VA events) or East Asian ancestry (3 VA events), VA2 or VA3 did not significantly improve the performance compared with VA1 alone.

#### Discussion

In this work, we assessed the contribution of PRS for cardio-vascular risk factors in the prediction of incident AF and VA in a large middle-aged population. We have validated the improvement in incident AF risk stratification provided by the combination of an AF PRS with the CHARGE-AF score and observed that the inclusion of multiple CV-PRS further improved discrimination. For incident VA, we observed that

a CAD PRS significantly improved risk stratification compared with sex and age alone, but the addition of the multiple CV-PRS only improved discrimination in individuals with prevalent IHD. We also demonstrated that our models using AF and CAD PRS for incident AF and VA risk prediction are potentially transferable in individuals of South Asian ancestry.

It has been reported previously that the combination of polygenic risk for AF with the CHARGE-AF clinical score improves incident AF risk prediction over CHARGE-AF alone in patients with and without cardiovascular diseases and risk factors.<sup>5</sup> Our work builds on these findings, demonstrating that inclusion of genetic predisposition for CV risk factors provides an incremental improvement in AF risk prediction in healthy middle-aged individuals of European ancestry. Results showed that genetically predicted shorter ventricular depolarization and repolarization times were associated with increased AF risk, confirming previous observations having also now performed adjustment for additional CV risk factors. 14 Finally, the contribution of MRI markers such as LVEF or LVESV highlights the role for genetically determined differences in ventricular structure in AF risk, potentially through atrial mechanical and cardiac ion channel remodeling.

Our sex-stratified analyses enabled the investigation of the potential contribution to risk prediction of CV-PRS in each sex separately, as well as the specific genetic architecture of AF and VA. The PRS for cardiovascular risk factors that significantly contributed to AF risk in men predominantly overlapped with those from the main analysis. However, the PRS for LVEF, T-pe interval, and resting HR were no longer significant in model AF3 and were replaced by the PRS for CAD and the PR interval. In women, inclusion of PRS for CV risk factors did not significantly contribute to AF risk prediction. The addition of the CAD PRS in the model for men suggests genetic predisposition to development of an ischemic substrate is an important contributor to AF risk compared with women, as previously reported,<sup>29</sup> as well as abnormalities in cardiac conduction, which have extensively been linked with AF.<sup>13</sup>

Sandhu and colleagues<sup>7</sup> recently demonstrated the added value of a CAD PRS to sex and age in stratifying patients with documented IHD on coronary angiography and CV comorbidities, according to SCD risk. Our study is the first to report the added value of a CAD PRS to sex and age for prediction of incident VA in the general population, and this improvement held when analyzing women and men separately. IHD is the most common risk factor for VA and SCD in middle-aged individuals, <sup>6</sup> and identification of individuals early in life with a higher genetic predisposition could improve sudden cardiac death (SCD) prevention strategies. Interestingly, our results did not show an added value for the CAD PRS to sex and age alone when performing the analysis separately in individuals with and without prevalent IHD. These findings suggest that although a CAD PRS associates with risk for developing IHD, it does not offer improvements in VA risk stratification when considering the underlying etiology for arrhythmia.

Beyond the presence of ischemia, the causes of malignant VA are multifactorial, including cardiomyopathies and inherited channel opathies, which might be reflected on ECG and MRI risk

factors through the effects of structural changes, including fibrosis and postmyocardial infarction remodeling.<sup>6</sup> In our work, we observed that the PRS for HF, QT dynamics during exercise, high-density lipoprotein (HDL), and QT interval remained significantly associated with incident VA risk after adjusting for sex, age, and the CAD PRS, but they did not provide an improvement in risk stratification value. This may be caused by small individual effect sizes. In sex-stratified analyses there were similar observations. However, when analyzing individuals with prevalent IHD, we observed that inclusion of the PRS for DBP and DCM significantly improved VA risk prediction. The incremental gain by including a DCM PRS could suggest an interaction of ischemic and nonischemic etiologies in genetically predisposed individuals that contributes to VA risk.<sup>7</sup> Thus, our results extend the observations of Sandhu et al<sup>7</sup> and warrant testing of these models in other cohorts including those considered clinically high risk.

We also tested the performance of the models trained using individuals with European ancestry in non-European ancestry groups. We observed that the AF and CAD PRS significantly contribute to incident AF and VA prediction, respectively, in South Asian ancestry individuals but not in individuals with African or East Asian ancestry. These findings suggest a good transferability of the AF PRS to a South Asian population and confirms previous observations for the generalisability of the CAD PRS.<sup>28</sup> The absence of a significant improvement in African and East Asian individuals could be caused by a smaller number of cases; however, they may also reflect a need for ancestry-specific PRS for these 2 populations.<sup>30</sup> Including multiple CV-PRS in AF3 did not improve the performance of AF2 in people of South Asian ancestry; however, it is of interest that the predictive value of CHARGE-AF alone in these individuals was better than AF3 (CHARGE-AF, AF PRS, and PRS for multiple cardiovascular risk factors) in persons of European ancestry. This may reflect a greater prevalence of advanced CV disease in these individuals that could lessen the additive effect of PRS (Supplemental Table S13).

Regarding the clinical implications of our findings, although the combined models are statistically significantly stronger than the clinical risk scores, the improvement is marginal. However, even a small improvement in predictive accuracy can be clinically relevant, particularly if it shifts an individual's risk classification from a lower to a higher risk category, as shown in our NRI results. Our results could inform the design of clinical studies to investigate the utility of these PRSs in patient cohorts and higher risk populations, to identify individuals who would benefit most from more intensive screening for earlier AF detection that would facilitate prompt initiation of anticoagulation.

# Strengths and limitations

A strength of this work is that we developed specific models for prediction of incident AF and VA, both in the overall population, and in men and women separately. Thus, the results are not biased by an a priori specific selection of PRS for each outcome. Moreover, we used one of the largest cohorts available with detailed phenotypic and genetic data and

Heart Rhythm, Vol ■, No ■, ■ 2024

relatively long follow-up. In addition, the inclusion of PRS for robust ECG and MRI risk markers allows an extended characterization of the genetic architecture of AF and VA risk.

There are also some limitations in our study. First, the study is limited to the UK Biobank cohort, which is known to have a healthy volunteer selection bias. Calculation of optimal PRS was performed independently from the samples used to train and test the models, thus minimizing the risk of overfitting. However, validation of these findings in other cohorts at different levels of risk and in other ethnicities will provide support for further generalizability. We used variants and effect sizes from multiancestry genome-wide association study (GWAS) whenever possible to optimize transferability across ancestries, following findings from previous studies. However, multiancestry GWAS on ECG and MRI traits are not currently available.

#### Conclusion

In this large middle-aged population-based cohort, the inclusion of PRS for CV risk factors provides an incremental improvement in prediction of incident AF risk when combined with the CHARGE-AF clinical score and an AF PRS. Regarding VA risk, although they did not improve the risk stratification value of sex, age, and a CAD PRS for incident VA prediction in the main analysis, they showed a significant contribution in individuals with IHD. Our results also indicate a good transferability of the European AF and CAD PRS for AF and VA risk prediction, respectively, in persons of South Asian ancestry.
