Abstract

We report the Imaging X-ray Polarimetry Explorer (IXPE) polarimetric and simultaneous multiwavelength observations of the high-energy-peaked BL Lacertae object (HBL) 1ES 1959+650, performed in 2022 October and 2023 August. In 2022 October, IXPE measured an average polarization degree $\Pi_X = 9.4\% \pm 1.6\%$ and an electric-vector position angle $\psi_X = 53^\circ \pm 5^\circ$. The polarized X-ray emission can be decomposed into a constant component, plus a rotating component, with the rotation velocity $\omega_{\text{EVPA}} = (-117 \pm 12) \text{ deg day}^{-1}$. In 2023 August, during a period of pronounced activity of the source, IXPE measured an average $\Pi_X = 12.4\% \pm 0.7\%$ and $\psi_X = 20^\circ \pm 2^\circ$, with evidence ($\sim 0.4\%$ chance probability) for a rapidly rotating component with $\omega_{\text{EVPA}} = 1864 \pm 34 \text{ deg day}^{-1}$. These findings suggest the presence of a helical magnetic field in the jet of 1ES 1959+650 or stochastic processes governing the field in turbulent plasma. Our multiwavelength campaigns from radio to X-ray reveal variability in both polarization and flux from optical to X-rays. We interpret the results in terms of a relatively slowly varying component dominating the radio and optical emission, while rapidly variable polarized components dominate the X-ray and provide minor contribution at optical wavelengths. The radio and optical data indicate that on parsec scales the magnetic field is primarily orthogonal to the jet direction. On the contrary, X-ray measurements show a magnetic field almost aligned with the parsec jet direction. Confronting with other IXPE observations, we guess that the magnetic field of HBLs on subparsec scale should be rather unstable, often changing its direction with respect to the Very Long Baseline Array jet.

Unified Astronomy Thesaurus concepts: BL Lacertae objects (158); Polarimetry (1278); Relativistic jets (1390); High energy astrophysics (739); Plasma astrophysics (1261); Spectropolarimetry (1973); Blazars (164); Black holes (162); Active galaxies (17)

1. Introduction

Blazars are active galactic nuclei (AGN) with a relativistic jet of plasma pointing within several degrees of the line of sight (e.g., R. D. Blandford & A. Königl 1979). Relativistic motion (with bulk Lorentz factors $\Gamma \sim 10$) beams the radiation (C. M. Urry & P. Padovani 1995), causing these objects to be the most luminous persistent extragalactic sources at

wavelengths from radio to TeV γ -ray. The nonthermal emission from the blazar jet can be extremely variable, on timescales as short as several minutes (F. Aharonian et al. 2007; M. Ackermann et al. 2016).

BL Lacertae objects are a class of blazars that exhibit little or no thermal emission, in lines or in continuum, in their near-IR, optical, and UV spectra. Hence, their spectral energy distribution (SED) is entirely dominated by nonthermal processes. High-energy-peaked BL Lac objects (HBLs) are a subclass with the SED of their synchrotron emission peaking at the X-ray energies.

The target of this investigation, 1ES 1959+650, is an HBL at redshift $z = 0.047$ (E. S. Perlman et al. 1996). It is among the first blazars detected at TeV energies (e.g., F. Aharonian et al. 2003), and it has been the target of several multifrequency campaigns (e.g., H. Krawczynski et al. 2004; G. Tagliaferri et al. 2008;

⁶² While the AAS journals adhere to and respect UN resolutions regarding the designations of territories (available at <http://www.un.org/press/en>), it is our policy to use the affiliations provided by our authors on published articles.

E. Aliu et al. 2014; MAGIC Collaboration et al. 2020a). Very Long Baseline Array (VLBA) images obtained between 2005 and 2009 (and similarly for Mrk 501 and Mrk 421) at 22 GHz (B. G. Piner et al. 2010) revealed a characteristic polarization structure of the jet: the electric-vector position angle (EVPA) was parallel to the jet axis (position angle $\sim 150^\circ$, measured north through east) in the “core” (upstream end on the images) of the jet, while on the edges it was closer to orthogonal. This pattern can be interpreted in terms of a structured (spine-sheath) jet (B. G. Piner et al. 2010). Later, higher-resolution VLBA images at 43 GHz measured the jet direction in the most compact region to be $128^\circ \pm 13^\circ$ (Z. R. Weaver et al. 2022).

The EVPA of the optical polarization of 1ES 1959+650, observed between 2009 and 2011, varied about a stable value of $\sim 150^\circ$ (i.e., parallel to the compact jet; M. Sorcia et al. 2013). The authors speculated that two components are responsible for the optical emission, with one nearly stable component with EVPA $\sim 150^\circ$ associated with the overall jet emission, and a time varying component, perhaps originating in shocks within the jet.

The light curves of 1ES 1959+650 between 2016 and 2017 contain a number of flares from radio to TeV energies. These flux variations and the SED can be explained by a model with two electron populations: one with a synchrotron component peaking at radio-IR frequencies and another, highly variable component peaking in the X-ray range, with the optical emission corresponding to the superposition of both emitting components (S. R. Patel et al. 2018; MAGIC Collaboration et al. 2020a, 2020b); but see also B. Kapanadze et al. (2018) and S. Chandra et al. (2021) for different interpretations.

The Imaging X-ray Polarimetry Explorer (IXPE; M. C. Weisskopf et al. 2022) observed 1ES 1959+650 twice during the first semester of scientific operations. Polarization was detected during the first pointing (2022 May) with the polarization degree (PD) $\Pi_X = 8.0\% \pm 2.3\%$, although only an upper limit ($\Pi_X < 5.1\%$, 99% confidence level, c.l.) was obtained from the second observation (2022 June) of the source (M. Errando et al. 2024). During the second campaign, optical polarization at a level of $\Pi_O \sim 5\%$ was measured.

IXPE also observed the HBLs Mrk 421, and Mrk 501 during the first semester of scientific operations, detecting linear polarization in all of them (L. Di Gesu et al. 2022; I. Liodakis et al. 2022). The Mrk 501 observations found an almost constant X-ray PD and EVPA. In contrast with the second campaign of 1ES 1959+650, the X-ray PD was measured to be a factor of 2–2.5 times higher than at optical wavelengths, and the X-ray EVPA was found to be close to the optical and radio values, and also close to the direction of the jet axis. This is compatible with a model in which particles are accelerated at a shock front, after which they lose energy, leading to an energy-stratified emission region (I. Liodakis et al. 2022).

The first IXPE observation of Mrk 421 (L. Di Gesu et al. 2022) revealed a similar phenomenology as in the case of Mrk 501, but without alignment of the X-ray and optical EVPAs. Two subsequent IXPE observations of Mrk 421 found a rotation of the EVPA (L. Di Gesu et al. 2023). At the time of the X-ray EVPA rotation, the radio and optical PDs were lower than the X-ray values, and did not show any significant variation. During the second year of IXPE observations, four additional HBL objects were observed: 1ES 0229+200 (S. R. Ehlert et al. 2023), PG 1553+113 (R. Middei et al. 2023b), PKS 2155-304 (P. M. Kouch et al. 2024). These

Table 1
Log of X-Ray Observations

X-Ray Observatory	Observation Start (UT)	Exposure (ks)
IXPE	2022-10-28 06:02	281.6
XMM-Newton	2022-10-28 17:11	17.0
NuSTAR	2022-10-31 00:16	17.8
Swift-XRT	2022-10-29 09:39	0.9
...	2022-10-30 03:08	0.7
...	2022-10-31 01:16	1.7
IXPE	2023-08-14 01:09	459.7
Swift-XRT	2023-08-14 17:52	1.7
...	2023-08-15 19:12	1.7
...	2023-08-16 01:26	1.0
...	2023-08-16 23:58	0.8
...	2023-08-18 20:05	1.1
...	2023-08-19 00:52	0.8

displayed behavior mostly consistent with that of Mrk 501. However, in the case of PG 1553+113, during the IXPE observation, an optical EVPA rotation was detected without a radio or X-ray counterpart.

Here, we report the results of two additional sets of IXPE and multiwavelength observations of 1ES 1959+650, one in 2022 late October and another in 2023 August. The latter campaign was triggered by an X-ray outburst (B. Kapanadze 2023).

2. Log of X-Ray Observations

The two sets of IXPE observations took place (1) between 2022 October 28 at 06:02 UT and 2022 October 31 at 12:16 UT (2022 October campaign); and (2) between 2023 August 14 at 01:09 UT and 2023 August 19 at 08:50 UT (2023 August campaign). During the 2022 October campaign, XMM-Newton observed the source starting on 2022 October 28 17:11 UT for 17.0 ks. MOS1 was operated in PrimePartialW2 mode with the thick filter, MOS2 in FastUncompressed mode with the medium filter, and p-n CCD in timing mode with the thick filter.

NuSTAR observed 1ES 1959+650 starting on 2022 October 31 at 00:16:09 UT for 17.8 ks, and Swift observed several times with the X-Ray Telescope (XRT), always operating in Windowed-Timing mode, and with the UVOT using all six filters.

During the 2023 August campaign, Swift observed the source with 1 day cadence with the XRT always in Windowed-Timing mode, and the UVOT using all six filters.

A summary of the X-ray observations is given in Table 1.

3. Data Analysis

3.1. IXPE Data

We used IXPE level 2 data, with photon-by-photon information on time of arrival, position, energy, and the Q and U Stokes parameters. We analyzed data using the publicly available IXPEOBSSIM software version 30.5.0 (L. Baldini et al. 2022). We extracted the source data from a circular region with a 1.2 radius centered on the source position, while we extracted background data from an annular region with 2.5 and 3.5 inner and outer radii, respectively. We used the `xpbin` procedure to obtain the polarization cube (PCUBE) and the Stokes parameter spectra (I , Q , and U); we subtracted the background by applying the procedure proposed in L. Baldini et al. (2022).

We generated source and background PCUBEs for each detector unit. Detector-by-detector spectra were produced for I , Q , U Stokes parameters using the PHAI, PHAQ, and PHAU methods in `xpbin` and applying calibration database version CALDB 20221020 and a background-to-source BACKSCALE ratio of 0.05. The weighted analysis algorithm proposed in A. Di Marco et al. (2022) was used with 075 response matrices for the spectral analysis. A light curve was produced starting with a bin size of 6 s. The time bins not contained in the good time intervals were rejected, while the others were grouped in order to obtain the final bin size.

3.2. *Swift*-XRT Data

We reduced *Swift*-XRT (D. N. Burrows et al. 2005) data using `xrtpipeline` version 0.13.4, included in the HEASOFT v6.25 package, and using the most recent available calibration files. Events with a grade 0–2 were selected for Window Timed (WT) data, and with a grade 0–12 for the photon counting mode. We used `xrtmkarf` to create the ancillary response files. Several *Swift*-XRT observations span more than a satellite orbit. In order to give a detailed light curve, we subdivided these observations on an orbit-by-orbit basis. The obtained source counting rate reported in the *Swift*-XRT light curve was then corrected for vignetting and for source signal lost in dead strips in WT mode.

3.3. *NuSTAR* Data

We made use of standard level 2 event files generated by the *NuSTAR* Science Operations Center and available from HEASARC archive. We reduced and analyzed *NuSTAR* data using the NUSTARDAS1 Data Analysis Software in the HEASOFT V6.29 package, adopting CALDB version 20211020 calibration files. We used the `nuproducts` tool to extract high-level science products for the source in the 3–20 keV energy range. The source events were selected from a circular extraction region of 30'' radius, while the background was computed in an annulus centered on the source with inner and outer radii of 50'' and 100'' respectively.

3.4. *XMM-Newton* Data

We employed the *XMM-Newton* Science Analysis System, version 18.0.0, to process the *XMM-Newton* data. Source events were extracted from a circular region with 30'' radius centered on the source, while background events were obtained from a circular region with 40'' radius, offset from the source. Spectra were rebinned to have at least 30 counts for each spectral bin.

3.5. *Swift*/UVOT Data

We analyzed *Swift*-UVOT (P. W. A. Roming et al. 2005) data using the HEASOFT `uvotimsum` and `uvotsource` procedures. Source flux was extracted through aperture photometry from a 5'' circular region, and the UV magnitudes were corrected with values from Y. C. Pei (1992). Fluxes were derived from magnitudes according to T. S. Poole et al. (2008).

3.6. Radio/Optical Data

During the IXPE observations, several ground-based telescopes at radio (10–225 GHz) and optical (BVRI bands) frequencies provided total flux and polarization measurements. These included the Effelsberg 100 m telescope, the Submillimeter

Array (SMA), Calar Alto Observatory, the LX-200 telescope operated by Saint Petersburg University, the Nordic Optical Telescope (NOT), the 1.8 m Perkins telescope owned by Boston University (Perkins Telescope Observatory), the T90 telescope at the Sierra Nevada Observatory (SNO), and the RoboPol 1.3 m telescope at Skinakas Observatory. Logs of optical and radio observations are given in Tables 2 and 3, respectively.

The Effelsberg 100 m telescope observations were taken at 10.45 and 17 GHz in 2023 July and August, as part of the QUIVER (monitoring the Stokes Q , U , I , and V emission of AGN jets in radio) monitoring program (A. Kraus et al. 2003; I. Myserlis et al. 2018). The SMA observations were obtained at 1.3 mm (225 GHz) on 2022 October 31, and several dates in 2023 August, within the SMA Monitoring of AGN with POLarization program. The observing setup involved orthogonally polarized receivers in full polarization mode. The polarized intensity, degree, and angle were derived from Stokes parameters I , Q , and U and calibrated using the MIR package⁶³ (R. J. Sault et al. 1995; D. P. Marrone & R. Rao 2008; R. A. Primiani et al. 2016).

The Calar Alto and Sierra Nevada observations were taken in R band using the CAFOS polarimeter and a set of polarized filters, respectively. Several observations were taken for several nights during each IXPE observation. For SNO, we used the weighted average of all the observations taken within the same night. The NOT observations were taken in the BVRI bands during both IXPE pointings, using the Alhambra Faint Object Spectrograph and Camera (ALFOSC). The observations and data reduction are described in detail in K. Nilsson et al. (2018). Additional photometric and polarimetric measurements in BVRI bands were obtained at the Perkins telescope (Flagstaff, AZ) from 2022 October 27 to 2022 November 1 using the PRISM camera. A general description of polarimetric observations can be found in S. G. Jorstad et al. (2010). The Skinakas observations were taken in R band during 2023 August using the four-channel RoboPol polarimeter mounted on the 1.3 m telescope (G. Panopoulou et al. 2015; D. Blinov et al. 2021). Finally, the LX-200 telescope provided R - and I -band total intensity and R -band polarimetric observations on 2022 October 30 and 2022 October 31, and BVRI photometry and R -band polarimetry during the 2023 August observation. A description of observational procedures and data reduction can be found in V. M. Larionov et al. (2008). More details on the IXPE-related multiwavelength observing strategy and data reduction can be found in I. Liodakis et al. (2022), R. Middei et al. (2023a), A. L. Peirson et al. (2023), P. M. Kouch et al. (2024), and L. Di Gesu et al. (2023). The R -band polarization measurements were corrected for dilution of the polarization by unpolarized host-galaxy starlight by subtracting its contribution within the apertures used by different observatories, following K. Nilsson et al. (2007) and T. Hovatta et al. (2016). For the remaining optical bands, we report the observed values.

4. Results

4.1. Light Curves and Hardness Ratios

The *Swift*-XRT and *Swift*-UVOT light curves are presented in Figure 1, covering the two observing campaigns. The first IXPE campaign was performed during a period of intermediate activity of the source, while the second was performed during a

4.2. Polarimetry

4.2.1. X-Ray Polarimetry—2022 October Campaign

During the 2022 October observation, IXPE detected an average X-ray PD of $9.4\% \pm 1.6\%$ and an EVPA of $53^\circ \pm 5^\circ$, obtained by integrating over the entire 3.3 day pointing and over the energy interval 2–8 keV. For comparison, the minimum detectable polarization (corresponding to 99% c.l.) for that period was 4.9%.

The X-ray polarimetric evolution is shown in Figure 4 in q, u space, together with the constant polarization model. The result of fitting with a constant polarization model in q, u space is reported in the left panel of Figure 5 as a function of the number of time bins of the polarimetric light curve; the probability that the constant polarization model is correct is reported in the same figure. For the majority of chosen numbers of bins (except in four cases), the probability that the hypothesis of constant polarization is true is below 5%. Therefore, we evaluated other models to describe the polarimetric data.

We investigated the possibility of global EVPA rotation during the observation, e.g., the case where EVPA rotation applies to the entire time span of observed X-ray emission. We applied the unbinned likelihood method reported in L. Di Gesu et al. (2023), and we obtained an average global EVPA rotation rate $\omega_{\text{EVPA}} = 5 \pm 4 \text{ deg day}^{-1}$ (error at the 68% c.l.); the rotation rate over the entire period is compatible with zero at 90% c.l.

The data reported in Figure 4, the IXPE observation of X-ray EVPA rotation in Mrk 421 (L. Di Gesu et al. 2023), and the claim of two components contributing to the optical polarization and to the broadband SED of 1ES 1959+650 motivated us to test two nested hypotheses: (a) The observed polarized X-rays have an EVPA that is steady, $\frac{d\psi}{dt} = 0$ (steady polarization case). (b) The emission has two superposed components: one with steady polarization and the other with variable EVPA with a constant rotation rate ω_{EVPA} (two-component model). The two-component model differs from the global EVPA rotation model by adopting the hypothesis that the EVPA rotation is not a global phenomenon of the entire X-ray emission of the blazar; rather, it applies to only a fraction of the observed emission. The outcome of the tests of the two hypotheses is given in Table 4, where we report the results of the minimization of the unbinned log-likelihood estimators explained in Appendix A.

Figure 1. Swift light curves. Top to bottom: UVOT V optical filter, UVOT UVW2 ultraviolet filter, XRT X-ray, and X-ray hardness ratio (evaluated adopting the 0.3–2 keV and the 2–10 keV bands). The IXPE observing periods are denoted with green areas.

Figure 2. IXPE 2–8 keV light curves. Left: 2022 October campaign. Right: 2023 August campaign.

We derive a probability of 1.1×10^{-3} that the two-component model provides a better fit to the data (with respect to the constant polarization model) by random chance. The method for evaluating the statistical significance of the unbinned log-likelihood analysis is reported in Appendix C. We have checked the results of the unbinned log-likelihood study by adopting a binned analysis and χ^2 statistics. Details of this check are reported in Appendix C. The reduced χ^2 for the two-component model is 1.1 for 13 time bins.

The chosen two-component model assumes that the polarization variability is uncorrelated with the flux variability that we observe. We also tried a slightly different model, still consisting of a steady plus a variable component. We assumed that the component responsible for the polarization variability also causes flux variability, while the constant polarization

component gives a steady contribution to the X-ray flux (flux-correlated two-component model). In this model, we added a parameter: the contribution of the constant component (component 1) to the count rate (r_1). By definition, r_1 cannot surpass the minimum source counting rate measured during the 2022 October observing period. In this model, there is no longer a degeneracy between R_1 and Π_1 , or between R_2 and Π_2 . Results of the fit are reported in Table 4. Note that the value of the r_1 parameter that minimizes the C estimator is at the upper bound of its allowed range (the minimum source counting rate during the observation).

The flux-correlated two-component model and the two-component model are not nested models, so we cannot compare these models directly. From the ΔC for the flux-correlated two-component model with respect to the steady

Figure 3. Radio and optical light curves and polarimetric measurements with ground-based telescopes. The 2022 October campaign in the left panel; the 2023 August campaign in the right panel. The panels from top to bottom show optical brightness, radio and optical PD, and radio and optical polarization angle. The duration of the IXPE observation is indicated by the gray shaded area.

Figure 4. Left panel: Polarimetric evolution for the 2022 October observation. The constant polarization model (dotted line) and the two-component model (continuous line) are superposed on the data points. Right panel: q vs. u plot for the 2022 October observation. The continuous line is the two-component model fitting function.

polarization model, and from ΔC for the two-component model with respect to the steady polarization model, we obtain that the probability of choosing the flux-correlated two-component model by chance from a sample of events with steady polarization is about 1.8 times lower than the probability to choose the two-component model by chance.

4.2.2. X-Ray Polarimetry—2023 August Campaign

During the 2023 August pointing, IXPE detected an average PD of $12.4\% \pm 0.7\%$ and an EVPA of $19.7^\circ \pm 1.7^\circ$. The measurements of q and u Stokes parameters as a function of time are reported in Figure 6. The fit with a constant polarization

model is reported as well. The χ^2 binned analysis shows that the polarization cannot be considered constant with time.

We searched for a rotating component adopting the two-component model, with negative results. In fact, the two-component model produces a circular pattern in q, u space, while data show an elongated structure (Figure 6, central panel). Finally, we tried the three-component model (the new model has a constant component and two counterrotating components; see Appendix B). This model produces an ellipse in the q, u plane; therefore, it could reproduce the elongated pattern observed in 2023 August. The three component model has two more parameters with respect to the two-component model: the ratio $\frac{R_2^* \Pi_2^*}{R_2 \Pi_2}$ (where R_2^* is the relative flux of the

Figure 5. Results of binned analysis fitting of the 2022 October polarimetric light curve. Fit was performed on the q and u Stokes light curves. Left panel: reduced χ^2 for the constant polarization model as a function of the number of time bins, and associated probability that the fit function is true. Central panel: reduced χ^2 for the two-component polarization model as a function of the number of time bins, and associated probability that the fit function is true. Right panel: difference between the χ^2 for the two-component model and the χ^2 for the constant component as a function of the number of time bins (details are in Appendix C).

Table 4

Parameters and Log-likelihood Minima for the Steady Polarization Model, for the Two-component Model, and for the Flux-correlated Two-component Model for the 2022 October Observation of IES 1959+650 with IXPE

Steady Polarization Model		Two-component Model		Flux-correlated Two-component Model	
C	−62.2	C	−81.8	C	−85.3
Π (%)	9.4 ± 1.6	$R_1 \Pi_1$ (%)	$8.5^{+1.6}_{-1.9}$	Π_1 (%)	10 ± 2
Ψ (deg)	53 ± 5	Ψ_1 (deg)	51 ± 6	Ψ_1 (deg)	50 ± 6
...	...	$R_2 \Pi_2$ (%)	4.9 ± 1.7	Π_2 (%)	$62^{+0.21}_{-0.48}$
...	...	$\Psi_2(t=0)$ (deg)	31 ± 21	$\Psi_2(t=0)$ (deg)	25 ± 21
...	...	ω_2 (deg day $^{-1}$)	-117 ± 12	ω_2 (deg day $^{-1}$)	-117 ± 12
...	...	...	...	r_1 (cts s $^{-1}$)	$0.71^{+0}_{-0.17}$

Note. C is the log-likelihood minimum, Π is the PD, and Ψ is the EVPA for the steady polarization model. The two-component model has five parameters: $R_1 \Pi_1$ is the product of the relative flux with the PD of component 1, and $R_2 \Pi_2$ is the same for component 2. Ψ_1 is the EVPA of component 1, $\Psi_2(t=0)$ is the EVPA of rotating component 2 at the beginning of the observation, and ω_2 is the angular velocity of the EVPA of the second component (see text). The flux-correlated two-component model has six parameters: Π_1 is the PD of component 1, and Π_2 is the same for component 2. Ψ_1 is the EVPA of component 1, $\Psi_2(t=0)$ is the EVPA of rotating component 2 at the beginning of the observation, ω_2 is the angular velocity of the EVPA of the second component, and r_1 is the count rate of the steady component.

counterrotating component, and Π_2^* is its PD), and the phase of the counterrotating component (see Appendix B for detail). In light of the pronounced flux variability during the observation, we have also searched for rotating components by dividing the sample into subintervals. We integrated data in windows whose lengths are half of the total observing time, and tried four time bins, shifting the bin by one-third of its size, to search for transient phenomena. Results for this staggered analysis are displayed in Figure 7.

We found a signal ($\Delta C = 26.6$ for 4 degrees of freedom, hereafter dof, plus the rotation-rate parameter, relative to the constant polarization model) at a rotation rate of 5.2 ± 0.1 turn day $^{-1}$ (one turn is a 360° rotation of the EVPA) for an integration window of length $\Delta t = 2.66$ days, starting 1.77 days from the beginning of the observation. We report the results of this fit in Table 5.

We note that, when integrating data within the same window, there is another signal ($\Delta C = 20.5$) for a rotation rate of 1.9 ± 0.1 turn day $^{-1}$.

We have validated the unbinned log-likelihood analysis with a binned χ^2 test, as reported in Appendix D. The chance probabilities are $\leq 4.0 \times 10^{-3}$ and 6.5% for the candidate frequencies at 5.2 ± 0.1 and 1.9 ± 0.1 turn day $^{-1}$, respectively.

We report the evaluation of the significance of the unbinned log-likelihood fit of the three-component model in Appendix D.

We report in Figure 8 (left panel) the X-ray PD and EVPA signals folded for a frequency of 5.2 ± 0.1 turn day $^{-1}$, accumulated for the entire window 3; and in Figure 8 (central panel) the corresponding q versus u plot.

The right panel of Figure 8 displays the folded polarimetric light curves in a 70° rotated q , u space. It shows that the modulated signal is almost unidimensional. We tested the hypothesis of an unidimensional oscillation by fixing the $\frac{R_2 \Pi_2}{R_2 \Pi_2 + R_1^2 \Pi_1^2}$ parameter to 0.5. With this choice, the three-component model describes a line in q , u space, with Stokes parameters oscillating around the center of the line. With this choice, $\Delta C = -25.3$ for the principal minimum at 5.2 day^{-1} rotating frequency; while $\Delta C = -20.5$ for the secondary minimum at 1.9 day^{-1} . In this case, ΔC has a χ^2 distribution with 3 dof when computed as a function of the EVPA rotation rate. The probability to detect by chance at least two such signals with $\Delta C \leq -20.5$ in the 2023 August observation is $\leq 2.5 \times 10^{-4}$.

We have also investigated whether the rotation rate could vary with some power of X-ray energy: $\omega = \omega_0 \left(\frac{E}{2 \text{ keV}} \right)^k$. For the 2022 October observation, we obtained $k = 0.1 \pm 0.1$; while for the 2023 August target of opportunity we obtained

Figure 6. Polarimetric analysis of the 2023 August IXPE data. Fit was performed on the q and u Stokes light curves. Left panel: q and u light curves, fit with a constant polarization model. Central panel: q vs. u scatter plot for the 2023 August period. Right panel: reduced χ^2 for the constant polarization model as a function of the number of time bins, and associated probability that the fit function is true.

Figure 7. Result of search for rotating EVPA for the 2023 August data. We report the minimum of the log-likelihood estimator C for each candidate value of the rotation rate. Model consists of three components (with a rotating plus a counterrotating component). Results are shown for staggered windows of integration, with size 2.66 days, each shifted from the previous one by 0.88 day. For increasing window identifier, C is increased by multiples of 30.

$k = 0.002 \pm 0.005$ (90% c.l.). For both observations, the result is compatible with a rotation rate that does not vary with energy (90% c.l.). We have tested with simulations whether gaps in the observation or the satellite pointing dithering could produce a spurious rotating signal at the frequency range of our analysis, but were unable to reproduce such a signal. Details are given in Appendix D.

4.2.3. Radio and Optical Polarimetry

During the 2022 October campaign, we measured a low degree of polarization of 1ES 1959+650 at 225 GHz: $\Pi_R = 1.3\% \pm 0.4\%$ at a position angle of $\psi_R = 140^\circ \pm 9^\circ$. At optical wavelengths, the flux varied on short timescales, but with a low amplitude of <0.1 mag. The average intrinsic R-band polarization of the source was $\Pi_O = 4.54\% \pm 0.7\%$ at EVPA $\psi_O = 152^\circ \pm 6^\circ$. All B , V , R , and I EVPAs are consistent within uncertainties and appear to vary in tandem. The jet direction prior to 2018 was $128^\circ \pm 13^\circ$ (Z. R. Weaver et al. 2022), although during the IXPE observations it was

Table 5
Parameters and Log-likelihood Minima for the Steady Polarization Model and for the Three-component Model with Two Counterrotating Components for the 2023 August Observation of 1ES 1959+650 with IXPE

Steady Polarization Model		Three-component Model with Two Counterrotating Components	
C	-187.4	C	-214.0
$\Pi(\%)$	9.9 ± 1.2	$R_1 \Pi_1(\%)$	9.9 ± 1.2
Ψ (deg)	19 ± 2	Ψ_1 (deg)	19 ± 4
...	...	$R_2 \Pi_2 + R_2^* \Pi_2^* (\%)$	5.3 ± 1.6
...	...	$\Psi_2(t=0)$ (deg)	65 ± 36
...	...	$\omega_2(\text{deg day}^{-1})$	1864 ± 34
...	...	$\frac{R_2 \Pi_2}{R_2 \Pi_2 + R_2^* \Pi_2^*} (\%)$	55 ± 17
...	...	$\Psi_2^*(t=0)$ (deg)	3 ± 36

Note. C is the log-likelihood minimum, Π is the PD, and Ψ is the EVPA of the steady polarized component. The three-component model with two counterrotating components has seven parameters: $R_1 \Pi_1$ is the product of the relative flux with the PD of component 1, Ψ_1 is the EVPA of component 1, $\Psi_2(t=0)$ and $\Psi_2^*(t=0)$ are the EVPAs of rotating and counterrotating components at the beginning of the observation, respectively, and ω_2 is the angular velocity of the EVPA of the rotating and counterrotating components. The other two parameters of the three-component model are $R_2 \Pi_2 + R_2^* \Pi_2^*$ and $\frac{R_2 \Pi_2}{R_2 \Pi_2 + R_2^* \Pi_2^*}$, where R_2 and R_2^* are the relative fluxes of the rotating and counterrotating components, respectively, and Π_2 and Π_2^* are the PD of the rotating and counterrotating components (see Appendix B, Equation (B2)).

(including uncertainties) $\sim 148^\circ$ – 168° (see below). Hence, the radio-optical polarization was roughly aligned with the jet axis within the rather large uncertainties.

While the source was in an outburst during the 2023 August campaign, we did not observe significant differences in its radio-optical polarization properties. The flux exhibited similar fast variations at low amplitudes. The radio (10–225 GHz) polarization was in the range $\Pi_R = 1\%$ – 4% with EVPA between $\psi_R = 138^\circ$ and 159° , with a typical uncertainty $\sigma_{\psi_R} = 6^\circ$. The R-band polarization increased from 4% to 6% during the IXPE observation, and then returned to $\sim 4\%$ afterward. The EVPA varied from 144° to 171° .

4.2.4. Millimeter-wave Imaging

The VLBA observes 1ES 1959+650 roughly monthly at a frequency of 43 GHz as part of the Blazars Entering the

Figure 8. Left panel: Folded polarimetric light curve of X-ray q and u Stokes parameters, for a folding frequency of $5.2 \pm 0.1 \text{ day}^{-1}$. Signal is accumulated for the entire window 3 of the 2023 August IXPE pointing (see text); the continuous line is the three-component model fitting function, while the dotted curve is the constant polarization model. Central panel: q vs. u plot for the folded signal; the ellipse (continuous line) is the three-component model fitting function. Right panel: folded polarimetric light curve of X-ray q_{rotated} and u_{rotated} Stokes parameters, rotated clockwise by 70° (the rotation angle corresponds to the angle of the ellipse (of the three-component model) major axis with respect to the q reference axis.)

Figure 9. VLBA images at 43 GHz of IES 1959+650 at three epochs near each IXPE observation, which occurred in 2022 October 28–31 and 2023 August 14–19. Both calendar dates and MJDs of the images are given. Three emission features present in all images, A0 (the “core”) J1, and J2, are marked, with their parameters listed in Table 6. Contours indicate total intensity in factors of 2, starting at 1.2% of the peak of $156 \text{ mJy beam}^{-1}$ in 2022 and $255 \text{ mJy beam}^{-1}$ in 2023. Color scale corresponds to linearly polarized intensity, with values indicated in each panel, while the polarization angle is denoted by the line segments in regions where polarization is detected. The elliptical restoring beam, with FWHM dimensions of $0.24 \times 0.17 \text{ mas}$, with major axis along position angle -10° , is displayed in the lower left corner of each panel.

Astrophysical Multi-Messenger Era monitoring program.⁶⁴ In Figure 9, we present two sets of three images each, constructed from data obtained near each of the two IXPE epochs. The angular resolution is of the order 0.15 mas , which translates to 0.14 pc projected on the sky for a Hubble constant of $70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. The imaging process involves a number of calibration steps, followed by iterations of image construction and self-calibration; see S. G. Jorstad et al. (2017) for a

thorough description of the analysis procedures. The object is weak at 43 GHz, limiting the dynamic range of the images such that the lowest contours are affected by noise. In order to represent the main features of each image, we fit the $u-v$ data with three components of circular Gaussian brightness distributions. Table 6 lists the parameters of these components at each epoch. The brightest feature, A0, is referred to as the “core.” In blazars, the core is considered stationary and near the upstream end of the jet. Knots (J1 and J2 in IES 1959+650) downstream of the core can either be quasi-stationary (common in BL Lac objects) or move away from the core (S. G. Jorstad et al. 2017). The only motion apparent in the images of Figure 9 is a downstream shift in the position of knot J1 between 2022 November 1 and 20 that does not continue to the next epoch 16 days later.

The jet direction (defined by a line between the centers of the core and knot J1) is $163^\circ \pm 5^\circ$ during the 2022 epochs and $155^\circ \pm 2^\circ$ in 2023. This is similar to the optical polarization angle. The degree of polarization of knot J1 tends to be high—up to $36\% \pm 16\%$ —although the uncertainties are large. The 43 GHz polarization angles of the core and knots, when detected, are within $\pm 10^\circ$ of the jet direction as well.

4.3. Energy Spectra

4.3.1. 2022 October Campaign

The X-ray spectrum obtained during the 2022 October campaign is shown in Figure 10. Data from Swift-XRT, IXPE, XMM-Newton, and NuSTAR are reported. An absorbed log-parabola model was fit to the data. Fit parameters are reported in Table 7. We obtained an unabsorbed flux of $(8.61 \pm 0.04) \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ in the 2–8 keV band (90% c.l.).

4.3.2. 2023 August Campaign

Swift observed the blazar six times during the 2023 August IXPE observation. We derived the spectrum by integrating IXPE data over 1.0 day around the peak emission on MJD 60172. The spectrum thus obtained is displayed in Figure 10, while the fit parameters are reported in Table 8. We obtained an unabsorbed flux of $(31.4 \pm 0.6) \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ (90% c.l.) in the 2–8 keV band.

5. Discussion

Our X-ray observations found 1ES 1959+650 to be at an intermediate flux level in 2022 October and in an outburst in 2023 August. During the second campaign, the X-ray spectrum gradually softened as the flux declined, except for a brief period of hardening corresponding to the flux peak on MJD 60172. This can be interpreted as gradual cooling of the electron population, interrupted by an episode of enhanced acceleration of electrons.

Optical photometry in 2023 August measured the brightness to be 1.2–1.5 mag higher than in 2022 October. In contrast, the millimeter-wave flux did not vary significantly between the two epochs. The Swift-UVOT flux in 2023 August did not exhibit the flaring episode that peaked on MJD 60172, as observed in the X-ray range with both IXPE and Swift-XRT. Swift-UVOT observations with optical filters only showed a weak flux peak on MJD 60172.

For both periods, the optical PD was in the 4%–6% range, and the EVPA fluctuated within 15° of 153° . IXPE observations in 2022 October and 2023 August measured the PD and EVPA to change from $9.4\% \pm 1.6\%$ to $12.4\% \pm 0.7\%$, and from $53^\circ \pm 5^\circ$ to $12.4^\circ \pm 0.7^\circ$, respectively.

Interestingly, the *R*-band PD in 2023 August increased from $\sim 4\%$ to $\sim 6\%$ from the beginning to the end of the IXPE pointing, while the EVPA varied more erratically by $\pm 10^\circ$. In contrast, IXPE found higher X-ray polarization, without any increasing PD trend; see Figure 6.

Our IXPE measurements have found significant X-ray polarization, with evidence for a component with rotating EVPA during both observations. We have found that the EVPA rotation rate does not vary with X-ray energy. Electrons incoherently gyrating in a magnetic field follow the field lines, with EVPA orthogonal to the local magnetic field direction as projected on the sky. Plasma moving in a helical magnetic field will produce synchrotron radiation with a rotating EVPA when observed close to the symmetry axis of the helix.

We have found some evidence for a rapidly rotating (~ 5.2 turn day^{-1} , 0.22% chance probability) component starting

1.77 days from the beginning of the 2023 August observation, which suggests that the rotation began with the peak in activity of the source. We found this signal only by adding a counterrotating component to the two-component model. In general, a rotating plus a counterrotating component describe an ellipse in the (q, u) plane (see Appendix B). In our case, the two components had almost the same flux, so that the model location in the (q, u) plane lies along a nearly straight line. Our three-component model reproduces the X-ray polarimetric variability observed for window 3 of the 2023 August IXPE pointing. However, we cannot establish if there was a counterrotating component responsible for the observed emission, or if, on the contrary, the counterrotating component only allowed us to describe a one-dimensional oscillation in the (q, u) plane caused by a different emission mechanism. A further rotating signal (~ 1.9 turn day^{-1}) with lower significance is found for the same exposure time during the 2023 August campaign.

Two previous papers (L. Di Gesu et al. 2023; D. E. Kim et al. 2024) have discussed how helical motion of plasma could explain the phenomenology observed in Mrk 421. For a helix, we can define the instantaneous rising angle (Θ_{rise}) of the plasma moving along the helical path (see Figure 11), while the angle formed by the instantaneous velocity vector of plasma moving along a helical path and the symmetry axis of the helix is denoted by $\Theta_{\text{rise}}^{\text{compl}}$. (By definition, $\Theta_{\text{rise}}^{\text{compl}} = \frac{\pi}{2} - \Theta_{\text{rise}}$.) We note that, for the rotating signal to be detected along the entire helical orbit, $\Theta_{\text{rise}}^{\text{compl}}$ should be smaller than the critical jet viewing angle $1/\Gamma_{\text{bulk}}$. Moreover, the observer’s viewing angle (Θ_{view} , measured with respect to the axis of the helix) should be lower than $\Theta_{\text{rise}}^{\text{compl}}$ for the Stokes parameters to execute a circular shape in the q, u plane:

$$\begin{cases} \Theta_{\text{rise}}^{\text{compl}} < 1/\Gamma_{\text{bulk}} \\ \Theta_{\text{view}} < \Theta_{\text{rise}}^{\text{compl}} \end{cases} \quad (1)$$

This implies that the plasma’s helical path is elongated along the jet axis.

Figure 10. Top: combined X-ray spectrum of 1ES 1959+560 during the 2022 October multiwavelength campaign, including Swift-XRT, IXPE, XMM-Newton, and NuSTAR data. Bottom: combined X-ray spectrum during the 2023 August campaign, including Swift-XRT and IXPE data integrated for 1.0 day around the peak emission on MJD 60172.

The EVPA rotation observed in the 2022 October X-ray data of 1ES 1959+650 can be explained by the hypothesis corresponding to Equation (1). We note, however, that the observed X-ray polarization evolution can be interpreted also with the flux-correlated two-component model. With this modeling, we obtained that the fitted flux of the constant

component corresponds to the maximum allowed value (see Table 4), possibly indicating that the line of sight was not inside the source emitting cone for the entire observation, $\Theta_{\text{view}} \sim \Theta_{\text{rise}}^{\text{compl}}$, or, alternatively, that the typical opening angle of the helix is comparable to (or slightly larger than) the emitting cone aperture: $\Theta_{\text{rise}}^{\text{compl}} \sim 1/\Gamma_{\text{bulk}}$.

Table 7

Log-parabola Model X-Ray Spectral Fit of the Combined 2022 October IXPE, NuSTAR, XMM-Newton, and Swift-XRT Data of 1ES 1959+650

$\frac{\chi^2}{\text{dof}}$	dof	N_{H} (10^{21} cm^{-2})	Π_{X} (%)	Ψ_{X} (deg)	α	β	E_{pivot} (keV)	N ($10^{-3} \text{ keV}^{-1} \text{ cm}^{-2}$)
1.22	1214	1.01	9.8 ± 1.2	50 ± 4	2.504 ± 0.005	0.323 ± 0.005	5	1.403 ± 0.005

Note. The number of degrees of freedom are denoted with dof; the column density N_{H} and pivot energy are held constant. Not shown in the table are the intercalibration factors with respect to XMM-Newton; for NUSTAR PFMA and PFMB, 1.14 ± 0.01 and 1.14 ± 0.01 , respectively; for IXPE DU1, DU2, DU3, 1.033 ± 0.005 , 0.991 ± 0.005 , and 0.936 ± 0.005 , respectively.

Table 8

X-Ray Spectral Fit of a Log-parabola Model to the Combined 2023 August IXPE and Swift-XRT Data for 1ES 1959+650

$\frac{\chi^2}{\text{dof}}$	dof	N_{H} (10^{21} cm^{-2})	Π_{X} (%)	Ψ_{X} (deg)	α	β	E_{pivot} (keV)	N ($10^{-3} \text{ keV}^{-1} \text{ cm}^{-2}$)
1.12	787	1.01	12.6 ± 1.3	22 ± 3	2.98 ± 0.02	0.80 ± 0.02	5	4.65 ± 0.06

Note. The number of degrees of freedom is denoted with dof; the column density N_{H} and pivot energy are held constant. The intercalibration factors, not shown in the table, are with Swift-XRT as reference: IXPE DU1, DU2, DU3, 0.873 ± 0.009 , 0.829 ± 0.009 , 0.793 ± 0.009 , respectively.

Figure 11. Helix viewed at 90° to the axis, illustrating the definition of the rising angle Θ_{rise} , the regions seen from above (shading by continuous lines), and regions seen from below (dashed lines). The jet axis corresponds to the vertical line.

The peculiar rotation of the EVPA observed in 2023 August cannot be explained with Equation (1). We also could not reproduce the observed behavior with the hypothesis that the our line of sight is outside $\Theta_{\text{rise}}^{\text{compl}}$:

$$\begin{cases} \Theta_{\text{rise}}^{\text{compl}} < 1/\Gamma_{\text{bulk}} \\ \Theta_{\text{view}} > \Theta_{\text{rise}}^{\text{compl}} \end{cases} \quad (2)$$

The evolution of rotated Stokes parameters in Figure 8 suggests that the polarimetric oscillation takes place in a single dimension. Alternatively, we have the unlikely case of two almost exactly counterrotating (and of similar flux) components combining to give rise to the observed polarimetric X-ray signal.

EVPA rotation components could be a sign of a stochastic process controlling the direction of the magnetic field. Rotations that vary the EVPA about a “preferred” value can be explained also by turbulent plasma whose field is partially ordered by a shock or by a helical component (A. P. Marscher 2014).

6. Interpretation

The two campaigns centered on IXPE observations of 1ES 1959+650 found different X-ray PDs and EVPAs, which indicates that the X-ray polarization is not simply associated with a fixed jet direction. We propose that the polarized X-ray emission was associated with localized regions during each of the two campaigns, although there were substantial differences. During both observations, we detected evidence for components with rotating EVPAs. Over the intermediate activity period observed during the 2022 October campaign, the EVPA rotation velocity was low ($\sim 0.3 \text{ turn day}^{-1}$). Our modeling of the IXPE data from the 2023 August campaign, during a major outburst of the source, instead found a fast rotation velocity ($\sim 5.2 \text{ turn day}^{-1}$, detected when integrating data over 2.66 days). Another difference between the two campaigns is that, in 2022 October, we only needed a constant and a single rotating component, while, in the 2023 August campaign, a counterrotating component with almost the same intensity as the rotating one is required for the rotating EVPA signal to be detected, resulting in an elongated elliptical path in q, u space. There may be an analogy with solar coronal loop observations (see, e.g., V. M. Nakariakov et al. 2016, and references therein): both rapidly decaying and undamped oscillations are detected. For coronal loops, continuous excitation of the oscillating system is invoked to explain the latter case.

Regarding optical polarization, our data confirm the presence of a dominant and persistent polarized emission component with a fixed EVPA direction, with other weak components contributing to minor changes of the EVPA. We observed for the X-ray outburst in 2023 August a gradual rise of the optical PD, and a coincident change of the optical EVPA. Moreover, optical and UV photometric measurements show that, over long time spans, the optical and X-ray emission both rose in 2023 August with respect to emission in 2022 October, and that the X-ray flux peak on MJD 60172 was observed in V band as

well. Therefore, a dominant and persistent optical emission component is observed, but the data suggest that the plasma responsible for the X-ray emission provides a minor contribution to the optical flux.

In contrast with the X-ray emission, the optical polarization vector in 2023 August was, on average, oriented in a direction similar to that measured in 2022 October, even though the optical flux on 2023 August was double the level of 2022 October. This discrepancy can be reconciled by assuming that the X-rays are emitted within small regions where the mean direction of the magnetic field is not perpendicular to the jet axis as measured at 43 GHz, while optical photons are emitted from larger regions where the average magnetic field is transverse to the jet axis; see below for proposed models.

Regarding the radio flux and polarization, our data set is rather sparse for the 2022 October period, while for the 2023 August campaign the cadence is daily. The average radio PD is lower than the optical value, while the EVPA almost matches that at optical wavelengths. This suggests that the main source of radio flux has the same general origin as the dominant and persistent emission observed at optical wavelengths.

B. G. Piner et al. (2010) measured the apparent speed of moving components near the core at 43 GHz in TeV-detected blazars, finding low apparent speeds (below $1c$) for 1ES 1959 +650, Mrk 421, and Mrk 501, implying a viewing angle $\Theta_{\text{view}} < \frac{1}{\Gamma_{\text{bulk}}^2 \beta}$, and $\Gamma_{\text{bulk}} \sim 3-5$. We argue for a similar scenario for the X-ray emission (see Equation (1)). At such a narrow viewing angle, the resolution of the VLBA images, ~ 0.2 mas, corresponds to parsec scales when deprojected.

Z. R. Weaver et al. (2022) display an image of the blazar obtained in 2018 July at 43 GHz, showing the core A0, and knots A1, A2, A3, A4. A line of sight very close to the jet direction explains the rather large apparent opening angle, as well as the bend to the north on kiloparsec scales (T. A. Rector et al. 2003), which can be a small bend amplified by projection effects if the viewing angle is near 0° . (The jet direction is obtained from the position angle of lines connecting the core to the other features; position angles vary from $124^\circ \pm 8^\circ$ to $163^\circ \pm 17^\circ$; Z. R. Weaver et al. 2022.) Our similar high-resolution 43 GHz VLBA images in 2022 and 2023 (Figure 9) contain two features, J1 and J2, southeast of the core, with the inner jet EVPA oriented in the jet direction, indicative of a mean magnetic field that is transverse to the jet on parsec scales.

Polarization measurements at 10.45, 17, 43, and 225 GHz are core dominated, and they represent the average jet polarization on parsec scales (the innermost jet region is obscured by self-absorption at the lower frequencies), with EVPA aligned with the jet direction. We surmise that the observed PD is low because of a dominant turbulent component of the magnetic field, with the electric-vector polarization angle reduced by vector-averaging over the broad jet apparent opening angle. The high-resolution images of the jet (see Figure 9) confirm that the EVPA is parallel to the jet. Feature J1 usually has a high PD, indicating a moderate degree of ordering of the magnetic field, while J2 is too close to the core to evaluate its PD.

At optical wavelengths, we also observe emission from a larger volume in the jet than at X-ray energies, with an EVPA within the range of directions of the broad jet. Some of the optical emission also comes from the inner jet region. Because of this, we observe global optical flux enhancement in 2023

Figure 12. X-ray polarization results (orange symbols) and comparison with radio-jet direction: purple area represents the projected radio jet reported in Z. R. Weaver et al. (2022); green area represents the mean radio jet direction from the position angle of knot J1.

August, with respect to 2022 October (with a peak observed in the V filter simultaneous with the X-ray maximum), and optical polarimetric variability.

X-rays are emitted from a more compact region very close to the site of the highest-energy particle acceleration, allowing us to probe the local magnetic field associated with the acceleration process. The X-ray EVPAs are almost orthogonal to the overall jet direction as defined by the VLBA images; see Figure 12 and Z. R. Weaver et al. (2022). Three rough sketches of possible scenarios are presented in Figures 13, 14, and 15 (see also A. P. Marscher et al. 2024). In Figure 13, we assume that plasma is accelerated by local magnetic reconnection in a turbulent zone where oppositely directed magnetic fields stochastically meet. Most X-rays and a small fraction of the observed optical photons are emitted in the magnetic reconnection region, with a polarization angle that is essentially random and unrelated to the jet direction. Farther downstream of the accelerating region, the magnetic field includes a component transverse to the jet axis. This could be the result of a weak helical or toroidal field component (M. Lyutikov et al. 2005) or mild compression by shocks (P. A. Hughes et al. 1985). Optical photons are also emitted in this region. The relatively long cooling time of electrons responsible for the optical emission smooths the flaring profile in the optical light curve (see F. Tavecchio 2021, for further discussion).

In an alternative scenario, sketched in Figure 14, the jet is twisted by a few degrees, amplified by projection effects owing to the small angle of the axis to the line of sight. The X-ray emission is produced close to the jet origin, with the particle acceleration mechanism unspecified. The jet bends such that the EVPA in the X-ray emitting region happens to lie roughly perpendicular to the downstream jet direction where the 43 GHz core is observed.

The cartoon in Figure 15 represents a scenario that includes a helical magnetic field in the X-ray emission region that could explain the rotating EVPA signals inferred from our analysis above. This could be incorporated into the first scenario

Figure 13. Sketch of possible model for a structured jet in IES 1959+650. The X-ray emission arises from a small volume in turbulent plasma where magnetic reconnection occurs, accelerating electrons to extremely high energies. The magnetic field is randomly oriented, with no relation to the jet direction. The optical and radio emission occur downstream, where a helical component of the magnetic field (or weak shocks) provides a net field direction transverse to the jet axis.

Figure 14. Sketch of a second possible model designed to explain observation of the jet in IES 1959+650. The jet is slightly twisted, with bending by less than a few degrees that is accentuated by projection effects. The magnetic field is locally transverse to the jet axis along the jet's length, owing to a weak helical field component or mild shocks. The X-ray emission arises from an upstream region with different EVPA (which is transverse to the field) than that of the lower-frequency emission radiated in the downstream regions.

(Figure 13) if there is a small helical field component in the magnetic reconnection region.

The variability we see in the X-ray EVPA is amplified by the effects of relativistic beaming, aberration, and Doppler shifts. We cannot state from our measurements alone whether the different magnetic field orientations (in X-ray with respect to optical and radio) are due to a spine-sheath structure of the jet (see, e.g., M. Georganopoulos & D. Kazanas 2003; G. Ghisellini et al. 2005; F. Tavecchio & G. Ghisellini 2008; and Figure 13), or if the magnetic field changes continuously from subparsec to parsec scales. In a previous short observation of 50 ks (in 2022 May), IXPE found a low-significance

Figure 15. Sketch of a third scenario for explaining the X-ray polarization of IES 1959+650. X-rays probe subparsec scale distances from the SMBH, which contain a helical magnetic field with a small pitch angle (or, alternatively, a turbulent magnetic field with mean direction along the jet axis). Arrows indicate mean direction of the magnetic field during each of our two IXPE observations; X-ray EVPA is perpendicular to the mean magnetic field (projected on the sky). VLBA images exhibit a mainly toroidal magnetic field on parsec scales.

polarimetric signal, and an EVPA almost aligned with the VLBA jet (M. Errando et al. 2024). IXPE has measured EVPAs lying almost parallel to the jet position angle in other HBLs: PKS 2155–304 (P. M. Kouch et al. 2024) and Mrk 501 (C.-T. J. Chen et al. 2024, after averaging the EVPAs over all six IXPE observations). The change of X-ray EVPA with respect to the VLBA jet position angle is rather erratic in Mrk 421: in 2022 May, the EVPA was $\sim 51^\circ$ from the VLBA jet axis (L. Di Gesu et al. 2022); in 2022 June, IXPE observed an EVPA rotation by more than 360° over ~ 5 days (L. Di Gesu et al. 2023); in 2022 December, the X-ray EVPA was almost perpendicular to the VLBA jet axis (D. E. Kim et al. 2024), and a rotation of the EVPA with a two-component model was detected, so we can apply the scenario depicted in Figure 15; the IXPE observations in 2023 December revealed an EVPA direction changing from parallel to shifted by $\sim 46^\circ$ with respect to the VLBA jet axis (W. P. Maksym et al. 2024, paper submitted).

7. Conclusions

Based on all of the IXPE observations of blazars, if HBL jets contain a helical magnetic field component on subparsec scales, the magnetic field appears not to have a stable configuration. This implies that we can observe different behavior of the

X-ray emission in different objects, and at different times in a single object. We can measure long rotations of the EVPA for the case of a magnetic field with symmetry axis along the line of sight (as in the case of Mrk 421 on 2022 June). If the helical magnetic field has a symmetry axis not perfectly aligned with the line of sight, we can still recognize EVPA rotations by applying the multicomponent model; in this case, we expect the average X-ray EVPA to be almost orthogonal to the VLBA jet axis. For large off-axis values of the magnetic field on subparsec scales, the EVPA could be parallel to the VLBA jet due to projection effects. We note that radio features in the VLBA images of 1ES 1959+650, PKS 2155–304, Mrk 421, and Mrk 501 generally move at subluminal speeds (B. G. Piner et al. 2008, 2010), implying that the radio jet is aligned within a few degrees of the line of sight. The turbulent magnetic field scenario on subparsec scales could be adopted too, even if it is disfavored as the explanation of the 2022 June IXPE observation of EVPA rotation in Mrk 421. The turbulence model predicts that EVPA rotation could be observed by chance, but the average EVPA should not necessarily be orthogonal to the VLBA jet direction.

The observed average X-ray EVPA of 1ES 1959+650 is transverse to the mean magnetic field direction. We have found variability of the EVPA from one observation to the next, possibly implying that the average magnetic field in the X-ray emitting region is time-variable.

Our results suggest the presence of either a helical magnetic field in the jet of 1ES 1959+650, and perhaps other HBLs, or stochastic processes controlling the direction of the magnetic field within the jet. Further data are needed to confirm this conclusion, define better the temporal distribution of the X-ray EVPA, define better the relationship between the X-ray and longer-wavelength emission regions, and determine whether stochastic or systematic processes dominate the X-ray EVPA variations.

model fitting requires only five independent parameters, e.g.: $R_1 q_1$, $R_1 u_1$, $(1 - R_1) q_2^0$, $(1 - R_1) u_2^0$, and ω . With a few steps, we obtain an expression involving PD and EVPA of the bicomponents:

$$S(R_1, \Pi_1, \Psi_1, \Pi_2, \Psi_2, \omega) = -2 \sum_i \ln[1 + \mu_i R_1 \Pi_1 (\cos(2\Psi_1) \cos(2\psi_i) + \sin(2\Psi_1) \sin(2\psi_i)) + \mu_i (1 - R_1) \Pi_2 (\cos(2\Psi_2^0) \cos(2(\psi_i - \omega t_i)) + \sin(2\Psi_2^0) \sin(2(\psi_i - \omega t_i)))] . \quad (\text{A3})$$

Appendix A

Likelihood Estimator for the Two-component Model

The two-component model assumes that the polarized emission is obtained with two independent components: the first (steady) component with a fixed PD Π_1 and angle Ψ_1 (EVPA does not rotate), and a second (rotating) component characterized by a rotating EVPA with a constant rotation velocity ω_2 , and fixed PD Π_2 ; the polarization angle of the rotating component at the beginning of the observation is denoted by $\Psi_2(t=0)$. In this simple model, parameters do not depend on energy. If the fluxes of the two components are F_1 and F_2 , respectively, we define the relative fluxes of the two components as $R_1 = F_1/(F_1 + F_2)$ and $R_2 = F_2/(F_1 + F_2)$. We can parameterize the two components with Stokes parameters q_1 , u_1 , $q_2(t)$, $u_2(t)$ (with Stokes parameters for the second component that vary with time) or q_1 , u_1 , q_2^0 , u_2^0 of the bicomponents, and with the angular velocity ω of the EVPA of the second component (where q_2^0 and u_2^0 are the Stokes parameters of the second component at $t=0$). We can generalize the event density proposed for the likelihood estimator in Equation (51) of H. L. Marshall (2021): The event density for the case of the two-component model should not be integrated over the time interval, because it changes with time owing to the polarization rotation. The event density in this case is

$$\begin{aligned} \lambda(E, \psi) = & [R_1(1 + \mu(E)q_1 \cos(2\psi) \\ & + \mu(E)u_1 \sin(2\psi)) \\ & + R_2(1 + \mu(E)q_2(t) \cos(2\psi) \\ & + \mu(E)u_2(t) \sin(2\psi))] f_E A_E dt dE d\psi , \quad (\text{A1}) \end{aligned}$$

where we use the same notation adopted in H. L. Marshall (2021). The Stokes parameters (q_2, u_2) describe a rotation of the EVPA, and can be written $q_2(t) = \Pi_2 \cos(2(\Psi_2^0 + \omega t))$ and $u_2(t) = \Pi_2 \sin(2(\Psi_2^0 + \omega t))$. Using the Werner formulas twice, performing the same steps used in H. L. Marshall (2021) to obtain their Equations (51) through (54), and in the assumption of no energy dependence of polarization, we can obtain an expression for the likelihood estimator of the two-component model:

$$\begin{aligned} -2 \sum_i \ln[1 + \mu_i R_1 q_1 \cos(2\psi_i) + \mu_i R_1 u_1 \sin(2\psi_i) \\ + \mu_i (1 - R_1) q_2^0 \cos(2(\psi_i - \omega t_i)) + \mu_i (1 - R_1) u_2^0 \sin(2(\psi_i - \omega t_i))] . \quad (\text{A2}) \end{aligned}$$

Here, u_2^0 , q_2^0 are the Stokes parameters for the rotating component evaluated at $t=0$. There are six physical parameters to describe the model (R_1 , u_1 , q_1 , u_2^0 , q_2^0 , ω), but

The last expression is the likelihood estimator used in this study.

We can rewrite Equation (A1) as

$$\lambda(E, \psi) = [1 + \mu(E)q_T(t) \cos(2\psi) + \mu(E)u_T(t) \sin(2\psi)] f_E A_E dt dE d\psi , \quad (\text{A4})$$

where $q_T(t) = R_1 q_1 + R_2 q_2(t)$, and $u_T(t) = R_1 u_1 + R_2 u_2(t)$. Equation (A4) shows the known Stokes summation rule for incoherent polarized components: at any given time, we can represent the two-component model in the (q, u) plane as a vector $(q_T(t), u_T(t))$ that is the weighted sum of (q_1, u_1) and $(q_2(t), u_2(t))$ with weights given by the relative fluxes R_1 and R_2 of the intervening components. For any given observation with a given exposure, the two-component model is represented in the (q, u) plane as a circle of the radius $R_2 \Pi_2$, and with the offset $R_1 \Pi_1$ from the origin of the coordinates. In general, the event density of a multicomponent model can be represented at any given time as the weighted sum of (q_i, u_i) with weights R_i corresponding to the relative flux of the i components:

$$\begin{pmatrix} q_T \\ u_T \end{pmatrix} = \sum_i R_i \begin{pmatrix} q_i \\ u_i \end{pmatrix} . \quad (\text{A5})$$

Appendix B

Adding a Counterrotating Component to the Two-component Model (Three-component Model with Two Counterrotating Components)

Following the vectorial representation in Equation (A5), we can evaluate the effect of a counterrotating component in the (q, u) plane (with the counterrotating component having opposite rotation velocity with respect to the rotating component). In the simple case of a rotating and counterrotating component with the same phase at $t=0$, the two components add together coherently because they have the same direction. After a quarter of a turn in the (q, u) plane, the two components have opposite directions, reducing the total PD. After a half turn in the (q, u) plane, the two components add coherently, but with an opposite direction with respect to the case at $t=0$. After three-quarters of a turn, the situation is analogous to the case at a quarter of a turn, but with an opposite direction. In general, a model with three components (a constant polarization component and both rotating and counterrotating components) draws an ellipse in the (q, u) plane. The orientation of the axes of the ellipse depends on the relative phase of the rotating and counterrotating components. In the special case of oppositely rotating components with the same relative fluxes,

the ellipse reduces to a segment in the (q, u) plane; and the polarization vector oscillates within the segment.

The event density for this model (the three-component model with two counterrotating components) can be evaluated directly using the formalism of Equation (A5), within which the event density can be written as

$$\begin{pmatrix} q_T \\ u_T \end{pmatrix} = R_1 \begin{pmatrix} q_1 \\ u_1 \end{pmatrix} + R_2 \begin{pmatrix} q_2(t) \\ u_2(t) \end{pmatrix} + R_2^* \begin{pmatrix} q_2^*(t) \\ u_2^*(t) \end{pmatrix}. \quad (\text{B1})$$

We can write the vectors (q_i, u_i) as the product of the PD of the i component and a unit vector $\hat{p}_i$ containing the information of the EVPA for the i component: $(q_i, u_i) = \Pi_i \hat{p}_i$. Expression (B1) can be rewritten as

$$\begin{aligned} \begin{pmatrix} q_T \\ u_T \end{pmatrix} &= R_1 \Pi_1 \hat{p}_1 + R_2 \Pi_2 \hat{p}_2 + R_2^* \Pi_2^* \hat{p}_2^* \\ &= R_1 \Pi_1 \hat{p}_1 + (R_2 \Pi_2 + R_2^* \Pi_2^*) \left[\frac{R_2 \Pi_2}{R_2 \Pi_2 + R_2^* \Pi_2^*} \hat{p}_2 + \left(1 - \frac{R_2 \Pi_2}{R_2 \Pi_2 + R_2^* \Pi_2^*} \right) \hat{p}_2^* \right]. \end{aligned} \quad (\text{B2})$$

Appendix C

Details of the Analysis of X-Ray Data for the 2022 October Observation

In order to check the result of the unbinned log-likelihood analysis, we applied the binned analysis and the χ^2 statistics for both the constant model and the two-component model. The results are reported in Figure 5. While the binned analysis is less sensitive, we determined that the difference of χ^2 for the two nested models is close to the difference of the log-likelihood obtained with the unbinned analysis. Therefore, our results are validated.

We used Monte Carlo simulations to investigate the statistical distribution of ΔC , where C is the log-likelihood minimum, in the case of sets of data simulated with constant polarization: The two-component model has five parameters (including a frequency), while the constant polarization model has two parameters. With the candidate frequency of the rotating component fixed, ΔC for the two-component model relative to the constant polarization model has a χ^2 distribution with 2 dof. We also verified the ΔC distribution on real data: we analyzed all the IXPE observations of pointlike, nonblazar sources with a count rate $< 25 \text{ count s}^{-1}$ performed within the first 2 yr of observations. Observations lasting more than 6 days were subdivided into slots at least 3 days long. We obtained a total of 142 slots. We tried frequencies from the base frequency ($0.5/T_{\text{exposure}}$, where the factor 0.5 comes from the fact that the EVPA is confined within a 180° range) up to 10 turn day^{-1} . With the exclusion of Cyg X-3, we obtained that the ΔC distribution follows a χ^2 distribution when computed as a function of EVPA rotating frequency. For Cyg X-3, we were able to reconstruct the orbital frequency from the frequency scan. Therefore, we consider the statistics and the procedure to be validated with both simulations and real data. Moreover, with an ad-hoc scan, we were able to reconstruct the spinning

frequency of the X-ray pulsar GX 301–2. We also applied the method to the IXPE observations of Mrk 421 on 2022 June. We obtained the same findings reported in L. Di Gesu et al. (2023). Finally, the method has been already used to find the EVPA rotation during the IXPE observation of Mrk 421 on 2022 December; and the result has been validated with χ^2 fit of X-ray polarimetric evolution of the source (D. E. Kim et al. 2024).

We estimate the number of trials from the frequency range we searched over (approximately 10 times the base frequency). While performing the frequency scan to minimize the log-likelihood estimator, we have to deal with random signals. Random signals in the frequency domain have a correlation width that corresponds to the base frequency, so the number of independent trials is the ratio of the frequency range divided by the frequency width of random signals. The scan on frequencies was performed for both positive and negative

frequencies; hence, the frequency range should be multiplied by a factor of 2. We then have 20 independent trial frequencies. The chance probability can be obtained by using the binomial distribution for at least a signal with $\Delta C \geq 19.6$ and 20 trials. We then derive a probability of 1.1×10^{-3} that the two-component model provides a better fit to the data (with respect to the constant polarization model) by random chance.

Appendix D

Details of the Analysis of X-Ray Data for the 2023 August Observation

We studied with Monte Carlo simulations the case of applying the three-component model to event lists simulated with a constant EVPA and PD. The probability $P(\Delta C^*, N)$ to find by chance at least one signal with ΔC^* from a sample of N extractions depends on the probability p^* of extracting a value of ΔC^* in a single trial (which can be computed from the χ^2 distribution with 4 dof): $P(\Delta C^*, N) = \sum_{k=1}^N B(k, p^*)$, where $B(k, p)$ is the binomial distribution for k successes, and p is the probability of having a success in a single trial. With the chosen window length (Δt), random signals have a frequency width of $0.5/\Delta t$ in the frequency scan reported in Figure 7; we have 42 independent trials per window. For a single window, we have $P(\Delta C = 26.6, N = 42) = 1.0 \times 10^{-3}$, and $P(\Delta C = 20.5, N = 42) = 1.6\%$. If we consider that the search was performed on four staggered windows, the number of independent trials should be multiplied by a factor of ≤ 4 . Therefore, the chance probabilities are $\leq 4.0 \times 10^{-3}$ and 6.5% for the candidate frequencies at 5.2 ± 0.1 and $1.9 \pm 0.1 \text{ turn day}^{-1}$, respectively.

We analyzed the folded polarimetric light curves reported in Figure 8 with a binned χ^2 method to validate the unbinned analysis for window 3. We tested the two nested hypotheses of the constant and three-component models. Results are shown in

Figure 16. Results of binned analysis fitting of the 2023 August polarimetric light curve. Fit was performed on the q and u Stokes light curves. Left panel: reduced χ^2 for the constant polarization model as a function of the number of time bins, and associated probability that the fit function is true. Central panel: reduced χ^2 for the three-component polarization model as a function of the number of time bins, and associated probability that the fit function is true. Right panel: difference between the χ^2 for the three-component model and the χ^2 for the constant component as a function of the number of time bins.

Figure 16 as a function of the number of time bins. The $\Delta\chi^2$ between the constant and three-component models is $\Delta\chi^2 \sim 25$, confirming the unbinned likelihood result.

We tested with simulations whether the gaps in the observation could produce a spurious rotating polarization signal, but we were unable to reproduce any such signal. We also investigated whether the satellite dithering strategy could result in some characteristic frequency. In fact, noisy readout pixels, or charge buildup in the Gas Electron Multiplier (L. Baldini et al. 2021), combined with satellite dithering, could generate spurious, time variable polarization. Moreover, a spurious polarization measurement can be obtained for a source with a projected image close to the detector boundaries (A. Di Marco et al. 2023). We analyzed attitude data of the IXPE satellite, and studied the angular displacements of the source position (in detector D1 frame) with respect to the x - and y -axis of the D1 frame, along the radial direction, and rotations about the normal axis. We found several typical frequencies: the lower frequencies are at 14.9 day^{-1} (the satellite orbital frequency) and at 64.9 day^{-1} , with similar strength (we also found secondary harmonics and a beat frequency at 50 day^{-1}), incompatible with our results. In order to verify the effect on polarization results, we executed a further analysis of our window 3 data subset, extending the frequency scan over the first main frequency. We found only a weak signal, with $\Delta C = -13.7$ peaking at 14.84 day^{-1} , that could be tentatively correlated with the dithering strategy. This weak signal obtained for window 3 is not confirmed over the entire integration, for which we should expect a cumulative amplitude. Hence, we conclude that the combined effect of dithering and charge buildup has a negligible effect on the polarization rotation for a source photon count rate of $\sim 2 \text{ cts s}^{-1}$.
