PCV7	7 valent pneumococcal conjugate vaccine
PCV13	13 valent pneumococcal conjugate vaccine
IgG	Immunoglobulin G
GMC	Geometric mean concentrations
IPD	Invasive pneumococcal disease

15  
16 **What's known on this subject:**

17 Premature infants have a higher risk of invasive pneumococcal disease and are more likely to  
18 have lower vaccine responses compared to term infants. The optimal primary schedule to  
19 generate protective concentrations of pneumococcal antibodies in preterm infants is  
20 unknown.  
21

22  
23 **What this study adds:**

24 This 13-valent pneumococcal conjugate vaccine schedule RCT in preterm infants  
25 demonstrated that fewer priming doses resulted in higher post-booster, but lower post-  
26 primary IgG concentrations. The optimum schedule for preterm infants depends when they  
27 are most at risk of invasive disease.

**Contributors' Statement Page:**

Dr A Kent coordinated the study, performed statistical analysis and drafted the initial manuscript.

Dr S Ladhani assisted with the design of the study, coordination of the study, critically reviewed the manuscript and approved the final manuscript as submitted.

Dr N Andrews approved the data collection tools, performed the statistically analysis, critically reviewed the manuscript and approved the final manuscript as submitted.

Dr T Scorrer, Prof A Pollard, Dr P Clarke, Dr S Hughes, Dr C Heal, Dr E Menson, Dr J Chang, Dr P Satodia, Dr A C Collinson, Dr N Pritchard and Dr S Faust were members of the trial steering committee, recruited participants and were responsible for data collection and study procedures at their sites. They critically reviewed the manuscript and approved the final manuscript as submitted.

Prof D Goldblatt supervised the analysis of all laboratory samples, critically reviewed the manuscript and approved the final manuscript as submitted.

Prof E Miller and Prof P T Heath were responsible for the concept and design of the study and the overall supervision of all aspects of the clinical trial. They critically reviewed the manuscript and approved the final manuscript as submitted.

## Abstract

### Background

Premature infants have a higher risk of invasive pneumococcal disease and are more likely to have lower vaccine responses compared to term infants. Increasingly, immunization schedules are including a reduced, 2-dose, pneumococcal conjugate vaccine (PCV) priming schedule.

We aimed to assess the immunogenicity of 3 commonly used PCV13 priming schedules in premature infants, and their response to a 12-month booster dose.

### Methods

Premature infants (<35 weeks gestation) were randomized to receive PCV13 at 2 and 4 months (reduced schedule); 2, 3 and 4 months (accelerated schedule); or 2, 4 and 6 months (extended schedule). All infants received a 12-month PCV13 booster. Serotype-specific pneumococcal immunoglobulin G (IgG) for PCV13 serotypes were measured by ELISA 1 month after primary and booster vaccinations.

### Results

A total of 210 infants (median birth gestation  $29^{+6}$  weeks, range  $23^{+2}$ - $34^{+6}$ ) were included. Following primary vaccination, 75% (95% CI 62-85), 88% (95% CI 76-95) and 97% (95% CI 87-99) of participants had protective antibody concentrations for at least half the PCV13 serotypes for the reduced, accelerated and extended schedules respectively. Following booster vaccination, participants receiving the extended schedule had significantly lower ( $p<0.05$ ) geometric mean concentrations compared with reduced (for 9/13 serotypes) and accelerated schedules (for 4/13 serotypes).

### Conclusions

Fewer priming doses of PCV13 resulted in lower post-primary concentrations but higher post-booster IgG concentrations than an extended schedule. The optimum vaccine schedule for preterm infants will therefore depend on when they are most at risk of invasive pneumococcal disease.

## Introduction

Premature infants are at increased risk of vaccine preventable diseases, including a two-fold risk of invasive pneumococcal disease (IPD) compared to term infants.[1–3]

In most industrialised countries with established pneumococcal immunization programmes, the 13-valent pneumococcal conjugate vaccine (PCV13) has superseded the 7-valent PCV and has been shown to be highly immunogenic in term infants.[4–6]

The immunogenicity of PCV13 in premature infants receiving a 2-3-4 and 12-month schedule was only recently reported and showed lower immunoglobulin G (IgG) concentrations for 8 serotypes after both primary and booster doses compared to term infants.[7] This lower immunogenicity is consistent with previous PCV7 studies [8–10] and is concerning because premature infants are also less likely to benefit from the protective maternal antibodies transferred during late pregnancy.

Additionally, national immunization programmes are increasingly including reduced (2) dose priming schedules.[11,12] These schedules are immunogenic in term infants and, with some vaccines, may even improve B cell memory and booster responses.[13–16] However, little is known about the immunogenicity of fewer primary doses in premature infants.

This randomized, controlled trial aimed to assess the immunogenicity of reduced, accelerated (intended to provide maximum early protection) and extended (doses administered over a longer period) PCV13 priming schedules in premature infants after completion of the primary series and after a 12-month booster.

## Patients and Methods

### Participants and recruitment

Premature infants were enrolled in a phase IV open-label randomized controlled trial from 12 UK centres between May 2012 and May 2013. Potentially eligible infants were identified by the clinical teams and parents were provided with information by the research teams. Infants were eligible for inclusion if they had a birth gestation less than 35<sup>+0</sup> weeks, had no contra-indications for vaccination as defined by Department of Health guidelines[17] and were between 7 and 12 weeks of age. Additionally, infants should not have received any other vaccinations (with the exceptions of BCG and hepatitis B). Information on the participants' past medical, medication and vaccination history was collected from the medical records using a standardised case report form.

Written informed consent was obtained from parents prior to enrolment. The study was approved by the East of England – Essex research ethics committee (REC reference 07/HO301.11) and registered on the EudraCT clinical trial database (2007-007535-23).

### Vaccination

Infants were randomly assigned (1:1:1) to receive PCV13 (Prevenar13; Pfizer, New York) at 2 and 4 months of age (reduced schedule - Group 1), at 2, 3 and 4 months of age (accelerated schedule - Group 2) or at 2, 4 and 6 months of age (extended schedule - Group 3)(supplementary table 1). A booster dose of PCV13 was administered to all infants at 12 months of age. Additionally, all participants received a combined diphtheria, tetanus, acellular pertussis, *Haemophilus influenzae* type b and inactivated polio vaccine (Pediaceel; Sanofi Pasteur MSD, Lyon, France) at 2, 3 and 4 months old, meningococcal C-CRM<sub>197</sub> vaccine (Menjugate; Novartis Vaccines, Siena, Italy) at 3 and 4 months of age and a combined measles, mumps and rubella vaccine (Priorix; GlaxoSmithKline Biologicals,

1  
2  
3 Rixensart, Belgium) and Hib-MenC-TT conjugate vaccine (Menitorix, GlaxoSmithKline  
4  
5 Biologicals, Rixensart, Belgium) at 12 months of age (supplementary table 1). Participants  
6  
7 were vaccinated in hospital if still receiving inpatient care. All vaccines were administered  
8  
9 intramuscularly.

10  
11 Computerised block randomization was stratified by centre and gestation (<30 or ≥30 weeks  
12  
13 gestation) and each centre was allocated blocks of sequential numbers (block size 18).

14  
15 Following consent the subject was allocated the next available study number for that centre  
16  
17 and gestational age cohort, and the appropriate sealed envelope containing the group  
18  
19 allocation opened. The study was not blinded to parents or clinical personnel.  
20  
21

#### 22 23 24 25 **Blood sampling and serological methods**

26  
27 Up to 3 mL of whole blood was obtained from each participant prior to the first vaccination  
28  
29 (baseline), 1 month following primary vaccination (at age 5 months for Groups 1 and 2  
30  
31 participants and at age 7 months for Group 3 participants), prior to and 1 month after booster  
32  
33 vaccination (12 and 13 months respectively) (supplementary table 1).

34  
35 Serological analysis was performed at the World Health Organisation reference laboratory for  
36  
37 pneumococcal serology, Institute of Child Health, London. Following extraction from whole  
38  
39 blood, sera were stored at -70°C prior to assay for pneumococcal serotype-specific  
40  
41 immunoglobulin G (IgG) concentrations for the PCV13 pneumococcal serotypes by enzyme-  
42  
43 linked immunosorbent assay (ELISA) as previously described.[18] The lower limit of assay  
44  
45 quantification was 0.15 µg/mL and IgG concentrations ≥0.35 µg/ml were considered  
46  
47 protective.[19]  
48  
49  
50

#### 51 52 53 54 **Safety analysis**

1  
2  
3 All participants were observed for immediate adverse reactions. Solicited systemic and local  
4  
5 adverse reactions were recorded by the infant's main caregiver for 7 days following each  
6  
7 vaccination. All AEs (including serious adverse events) were recorded for 28 days after each  
8  
9 vaccination using an adverse event (AE) diary. Parents had access to a 24-hour telephone  
10  
11 contact number for AE reporting.  
12  
13

### 14 15 16 **Statistical analysis**

17  
18 The primary objectives were to assess IgG geometric mean concentrations (GMCs) and the  
19  
20 proportion of infants with protective serotype-specific antibody concentrations for PCV13  
21  
22 serotypes at 1 month after completion of the primary vaccination course, according to the 3  
23  
24 schedules. The main secondary objectives were to assess differences in serotype-specific IgG  
25  
26 GMC and seroprotection rates between schedules prior to and following booster vaccination  
27  
28 at 12 months of age; and to quantify the percentage of children experiencing fever, local  
29  
30 reactions and non-febrile systemic reactions within 7 days following each vaccine dose.  
31  
32

33  
34 Pre-trial sample size calculations estimated a minimum of 60 infants in each group to detect  
35  
36 at least a 2 fold difference between groups after primary immunization, with 80% power and  
37  
38 5% significance. Based on published data, the standard deviation of IgG responses was  
39  
40 estimated be 0.6 log<sub>10</sub> units.[20] To allow for drop out of subjects over the course of the  
41  
42 study and the challenges of obtaining blood samples from very premature infants, we aimed  
43  
44 to recruit 210 infants.  
45  
46

47  
48 Data were analyzed using a modified intention to treat analysis including all infants who  
49  
50 received a dose of PCV13 and from whom at least one post-vaccination blood sample was  
51  
52 obtained. GMCs and 95% confidence intervals (CI) were calculated for each sampling time  
53  
54 point, along with the proportion of infants achieving protective antibody concentrations and  
55  
56  
57  
58  
59  
60

1  
2  
3 binominal CI. Results below the lower limit of quantification (LLQ) were taken to be half  
4  
5 the LLQ for computational purposes.  
6

7  
8 Statistical comparison of antibody concentrations and the proportion of participants with  
9  
10 protective concentrations or AEs between the 3 trial arms were performed using the Student's  
11  
12 t-test and the  $\chi^2$ -test or Fisher's exact test, as appropriate. Statistical significance was defined  
13  
14 as  $p < 0.05$ . To facilitate comparisons we have analysed schedules based on the proportions  
15  
16 achieving adequate protection for at least half of the serotypes. The number of serotypes with  
17  
18 protective concentrations per participant were compared using the non-parametric Kruskal-  
19  
20 Wallis one-way analysis of variance test.  
21

22  
23 Logistic regression was used to examine the effect of gestation, the receipt of antenatal or  
24  
25 postnatal steroids, blood transfusion, BCG vaccination, early post-vaccination paracetamol  
26  
27 and the presence of chronic lung disease (CLD, defined as requiring oxygen or respiratory  
28  
29 support at 28 days of age) on seroprotection. Analysis was adjusted for gestation. For post-  
30  
31 primary vaccination results multivariable linear regression using log-transformed values was  
32  
33 performed (adjusting for group and gestation). Linear regression was not performed on  
34  
35 baseline IgG concentrations due to the large number of results below the LLQ.  
36  
37  
38  
39  
40

41 All data were analyzed using STATA version 13 (Stata Inc).  
42

## Results

A total of 210 infants were recruited. 199 participants (94.7%) completed the primary phase (primary endpoint) and 194 (92.4%) completed the entire study (Figure 1). 2 participants died of causes unrelated to the trial. The majority of infants who did not meet the inclusion criteria were outside the study age range or were too unstable for vaccination. A second group of infants was excluded for logistical reasons - many were transferred to their local neonatal unit prior to their first vaccination (Figure 1).

The characteristics of randomized infants were similar between groups (Table 1) with a median birth gestation of 29<sup>+6</sup> (range, 23<sup>+2</sup>-34<sup>+6</sup>) weeks and median birth weight of 1388g (range: 450-3390g). 112 vaccinations were administered to hospitalized participants.

### Primary vaccination

At baseline participants had very low antibody concentrations for all pneumococcal serotypes (Table 2, supplementary table 2). The highest IgG GMCs (for all participants) were seen for serotypes 14 (0.26 µg/mL) and 19A (0.19 µg/mL).

Following the primary vaccination course, substantial increases in antibody concentrations were seen for all serotypes and all groups. There was considerable variation between serotypes with IgG GMCs ranging from 0.16 µg/mL for serotype 6B (reduced schedule) to 8.49 µg/mL for serotype 14 (extended schedule) (Figure 2; Supplementary Table 3).

The primary schedule had a significant impact on vaccine immunogenicity. Lack of seroprotection for more than half the PCV13 serotypes was seen in 25%, 12% and 3% of participants receiving the reduced, accelerated and extended schedules respectively (p<0.001, supplementary figure 1 and supplementary table 4).

1  
2  
3 Participants receiving the extended schedule had higher IgG GMCs compared with the  
4  
5 reduced schedule for 11 serotypes and accelerated schedule for 7 serotypes. The accelerated  
6  
7 schedule was superior to the reduced schedule for 4 serotypes (Figure 2, Table 2;  
8  
9 Supplementary table 3).

### 14 **Booster vaccination**

16 At 12 months of age, waning of pneumococcal antibody concentrations was evident with low  
17  
18 rates of seroprotection against individual serotypes (Table 3; Supplementary table 5).

20 Antibody concentrations remained significantly higher in those who had received the  
21  
22 extended schedule compared with reduced (for 10 serotypes) or accelerated schedules (for 11  
23  
24 serotypes), the accelerated schedule was superior to the reduced schedule for one serotype  
25  
26 only.  
27

31 Following booster vaccination a high proportion of infants achieved protective concentrations  
32  
33 (Table 3). As at previous time points, significant variation in antibody concentrations  
34  
35 between serotypes and groups was apparent (Figure 3). In contrast to post-primary  
36  
37 vaccination responses, participants receiving the extended schedule had lower GMCs  
38  
39 compared with the reduced (for 9 serotypes) and accelerated schedules (for 4 serotypes). The  
40  
41 accelerated schedule was inferior to the reduced schedule for one serotype (19A)  
42  
43 (supplementary table 6). Infants who received the extended schedule had lower fold  
44  
45 increases in concentrations following booster vaccination than the other groups  
46  
47 (supplementary figure 2).  
48  
49  
50

### 54 **Predictors of antibody concentrations**

55  
56  
57  
58  
59  
60

1  
2  
3 Increased odds of seroprotection at 2 months of age were seen with each week of increased  
4 gestation for 4 serotypes: 6A (OR 1.34, 95% CI 1.12-1.60; p=0.001), 14 (OR 1.25, 95% CI  
5 1.12-1.41; p<0.001), 19A (OR 1.27, 95% CI 1.12-1.45; p<0.001) and 19F (OR 1.29, 95% CI  
6 1.09-1.52; p=0.003). Later gestation was associated with an increase in post primary  
7 vaccination IgG concentrations for 3 serotypes: 1 (6% increase per week, 95% CI 0.9-12;  
8 p=0.021), 3 (8% increase per week, 95% CI 4-14, p<0.001) and 7F (8% increase per week,  
9 95% CI 3-13; p=0.002).

10  
11  
12 Receipt of antenatal steroids was associated with decreased odds of seroprotection at 2  
13 months for 4 serotypes: 5 (OR 0.09, 95% CI 0.01-0.83; p=0.033), 6A (OR 0.26, 95% CI 0.10-  
14 0.69; p=0.006), 19A (OR 0.19, 95% CI 0.08-0.45; p<0.001 and 23F (OR 0.23, 95% CI 0.06-  
15 0.80, p=0.021). Additionally, post-primary vaccination serotype-specific IgG GMCs for  
16 serotypes 1, 4 and 9V were reduced in infants who had been exposed to antenatal steroids.  
17 At no time-points were antenatal steroids associated with higher antibody concentrations.

18  
19  
20 Pre- or post-primary protective concentrations were not associated with any other factors in  
21 regression analysis. An insufficient number of infants (14) received postnatal steroids to  
22 analyse any effect. Serotype-specific antibody concentrations after the 12-month PCV13  
23 booster were affected by priming schedule and pre-existing antibody levels only.

48  
49 There were no significant differences in the frequency or severity of local and systemic AEs  
50 between vaccination schedules at any time-point. Altogether 77 serious adverse events  
51 (SAEs) were reported (including the 2 deaths). SAEs were predominantly acute respiratory  
52 infections. There was 1 possibly related (suspected) unexpected serious adverse reaction  
53

2  
3 from each randomized group: 2 participants had necrotising enterocolitis within a week of  
4  
5 vaccination and 1 participant had post-vaccination cardiorespiratory instability requiring  
6  
7 readmission; all 3 infants made a good recovery.  
8  
9

## 10 11 **Discussion**

12  
13 This is the first study to compare different PCV13 schedules in premature infants and  
14  
15 demonstrates the need for early and effective immunization strategies for this vulnerable  
16  
17 group, given their very low pre-immunization antibody concentrations. Our results indicate  
18  
19 that most preterm infants can achieve seroprotective antibody concentrations for the  
20  
21 serotypes in PCV13 regardless of the primary schedule administered, especially after the 12-  
22  
23 month booster, but the magnitude of their immunological response is dependent on the  
24  
25 primary schedule they receive.  
26  
27  
28  
29  
30  
31

32 Serotype-specific responses varied, with lower IgG GMCs achieved for serotypes 3, 5 and 6B  
33  
34 after the primary course and for serotypes 3, 9V and 18C after the booster dose; these  
35  
36 findings are consistent with those observed in term infants.[4,21] However, when compared  
37  
38 with previous term (PCV13) and preterm (PCV7) studies, antibody concentrations after  
39  
40 primary and booster vaccination are lower overall, resulting in lower seroprotection following  
41  
42 primary vaccination.[4,5,8,9,22]  
43  
44  
45  
46

47 Similarly, compared with the recent PCV13 preterm study[7], lower IgG GMCs and  
48  
49 seroprotection rates were seen for all serotypes. These differences may be due to the  
50  
51 different laboratory testing methodology for serotype-specific antibody concentrations, but  
52  
53 potential biological explanations include interactions with concurrently administered  
54  
55 vaccines, the younger gestation of our cohort or our broad inclusion criteria encompassing  
56  
57  
58  
59  
60

1  
2  
3 infants with complex medical problems – representative of the preterm population.

4  
5 Additionally, Martinon-Torres *et al.* did not report baseline IgG concentrations which may  
6  
7 differ between countries and impact on post-vaccination concentrations.[7]  
8  
9

10  
11 When comparing schedules within our cohort, the most striking finding was the contrasting  
12  
13 immunogenicity of the 3 schedules at different time points, with the reduced dose schedule  
14  
15 generating inferior antibody concentrations after the primary course but superior antibody  
16  
17 concentrations after the booster dose. The higher post-primary IgG GMCs following 3 doses  
18  
19 (compared with 2 doses) is consistent with two meta-analyses of primary schedules in term  
20  
21 infants.[23,24] Of the 3-dose schedules, higher antibody concentrations were seen in  
22  
23 premature infants receiving the extended schedule. This was not observed in the meta-  
24  
25 analyses of term infant responses but an older age at final vaccination may be more important  
26  
27 in premature infants as it will allow further maturation of their immune system.[25,26]  
28  
29 However, this needs to be set against the optimal age at which protection is required in this  
30  
31 population. Several studies have indicated an increased susceptibility of IPD in babies born  
32  
33 prematurely when compared with term infants; this risk appears maximal in the first 6 months  
34  
35 of life.[1–3]  
36  
37  
38  
39  
40  
41  
42

43 The differences in response to the booster dose was unexpected as the type of priming  
44  
45 schedule has not been consistently shown to affect the generation of immunological memory  
46  
47 and PCV booster vaccine responses in term infants.[23,27] The improved post-booster  
48  
49 immunogenicity of fewer priming doses is well described for meningococcal C conjugate  
50  
51 vaccines and is thought to be due to lower total antigen exposure favouring differentiation of  
52  
53 B lymphoblasts into memory B cells instead of antibody-generating plasma cells.[14,15] In  
54  
55 pneumococcal conjugate vaccines, a study of Fijian infants receiving one PCV7 priming dose  
56  
57  
58  
59  
60

1  
2  
3 followed by the 23-valent pneumococcal polysaccharide vaccine (PPV23) at 12 months had  
4 higher IgG GMC for serotypes 4, 9V, 19F compared with those who had been primed with  
5 two or three PCV7 doses.[13] Similarly, infants receiving a lower antigen-containing  
6 investigational tetravalent PCV for priming had higher booster responses than those who had  
7 received the higher antigen-containing preparation.[28] However, it should be noted that a  
8 statistically significant difference between the reduced and accelerated schedule groups was  
9 observed for only one serotype.  
10  
11  
12  
13  
14  
15  
16  
17  
18  
19

20 Despite seroprotective concentrations, infants who had received the extended schedule had  
21 lower fold increases in antibody concentrations following booster vaccination than those  
22 receiving either the reduced dose or accelerated schedules suggesting that the higher pre-  
23 booster antibody concentrations at 12 months may have interfered with booster responses.  
24  
25  
26  
27  
28

29 This effect has been observed following booster doses for other vaccines and several  
30 hypotheses have been proposed including the formation of immune complexes consisting of  
31 pre-existing antibody and vaccine antigen resulting in less available vaccine antigen, and B  
32 cell receptor mediated negative feedback mechanisms, analogous to those described for high  
33 maternal antibody concentrations impairing primary vaccine responses.[29–33]  
34  
35  
36  
37  
38  
39

40 Within our cohort of premature infants, increasing birth gestation was associated with  
41 increased immunogenicity. This has previously been described for other vaccines and  
42 reflects deficiencies in both the innate and adaptive immune systems in these more premature  
43 infants.[34–39]  
44  
45  
46  
47  
48

## 49 50 51 **Limitations**

52 The study had some potential limitations. The different ages of infants at blood sampling  
53 between the groups must be considered when comparing primary schedules; the antibody  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 concentrations at 7 months for babies in Groups 1 and 2 are not known. It is possible, that  
4 infants in those groups may have had a rise in their antibody concentrations between their 5  
5 month sample and 7 months of age due to natural exposure.[40] However, a recent study  
6 comparing schedules in term infants which sampled some infants at both 5 and 8 months did  
7 not find a rise in antibodies between these ages.[27] We also did not measure antibody  
8 concentrations beyond 13 months of age.

9  
10 As the objectives of this study were to look at schedule differences within the premature  
11 population we did not include a term comparator group, however lower antibody  
12 concentrations were seen in our cohort when compared with a recent cohort of term infants in  
13 the UK who received a reduced dose schedule, which was analyzed in the same  
14 laboratory.[22]

15  
16 Additionally, we did not include any assessment of functional activity of the antibodies  
17 detected. Opsonophagocytic antibody titres may have allowed us to assess the potential  
18 clinical impact of schedule differences in more detail and should be considered in future  
19 studies. A previous meta-analysis of primary PCV schedules in term infants has shown a  
20 good relationship between ELISA measured IgG concentrations and opsonophagocytic  
21 antibody titres, however an analysis of serotype-specific OPA values did not find a consistent  
22 protective OPA titre across all vaccine serotypes.[24,41]

## 23 24 25 **Conclusion**

26  
27 PCV13 is well tolerated in premature infants. Different priming schedules result in higher  
28 IgG concentrations at different times during the first 13 months of life. We believe that such  
29 data will be of benefit to those planning or providing pneumococcal vaccines to preterm  
30 infants and will enable them to consider this in the context of their own immunization  
31 programmes and epidemiological situations.

## Supplementary tables

Supplementary table 1: Study design. DTaP-IPV-Hib: MenC: Meningococcal serogroup C. V: visit. \*blood sample.

Supplementary table 2. Pneumococcal IgG GMCs at baseline (2 months of age) and number of concentrations above the lower limit of quantification for the assay (0.15 µg/mL). There were no significant differences between groups.

Supplementary table 3. IgG GMCs following primary immunization course for each serotype and group. *a b c*:  $p < 0.05$  comparing reduced and accelerated, accelerated and extended, and reduced and extended schedules respectively; \* $p < 0.001$

Supplementary table 4. Number of serotypes against which individuals attained seroprotection following primary vaccinations. n (%)

Supplementary table 5. IgG GMCs prior to booster vaccination (12 months old) for each serotype by group. *a b c*:  $p < 0.05$  comparing reduced and accelerated, accelerated and extended, and reduced and extended schedules respectively; \* $p < 0.001$

Supplementary table 6. IgG GMCs following booster vaccination for each serotype by group. *a b c*:  $p < 0.05$  comparing reduced and accelerated, accelerated and extended, and reduced and extended schedules respectively; \* $p < 0.001$

### Checklist of items to include when reporting a randomized trial (56-58)

PAPER SECTION And topic	Item	Description	Reported on page #
<i>TITLE &amp; ABSTRACT</i>	1	<a href="#">How participants were allocated to interventions</a> (e.g., "random allocation", "randomized", or "randomly assigned").	
<i>INTRODUCTION</i> Background	2	<a href="#">Scientific background and explanation of rationale.</a>	
<i>METHODS</i> Participants	3	<a href="#">Eligibility criteria for participants</a> and the <a href="#">settings and locations where the data were collected.</a>	
Interventions	4	<a href="#">Precise details of the interventions intended for each group and how and when they were actually administered.</a>	
Objectives	5	<a href="#">Specific objectives and hypotheses.</a>	
Outcomes	6	<a href="#">Clearly defined primary and secondary outcome measures</a> and, when applicable, any <a href="#">methods used to enhance the quality of measurements</a> (e.g., multiple observations, training of assessors).	
Sample size	7	<a href="#">How sample size was determined</a> and, when applicable, <a href="#">explanation of any interim analyses and stopping rules.</a>	
Randomization -- Sequence generation	8	<a href="#">Method used to generate the random allocation sequence</a> , including <a href="#">details of any restriction</a> (e.g., blocking, stratification).	
Randomization -- Allocation concealment	9	<a href="#">Method used to implement the random allocation sequence</a> (e.g., numbered containers or central telephone), clarifying whether the sequence was concealed until interventions were assigned.	
Randomization -- Implementation	10	<a href="#">Who generated the allocation sequence, who enrolled participants, and who assigned participants to their groups.</a>	
Blinding (masking)	11	<a href="#">Whether or not participants, those administering the interventions, and those assessing the outcomes were blinded to group assignment.</a> When relevant, <a href="#">how the success of blinding was evaluated.</a>	
Statistical methods	12	<a href="#">Statistical methods used to compare groups for primary outcome(s); Methods for additional analyses.</a> such as subgroup analyses and adjusted analyses.	
RESULTS Participant flow	13	<a href="#">Flow of participants through each stage</a> (a diagram is strongly recommended). Specifically, for each group report the numbers of participants randomly assigned, receiving intended treatment, completing the study protocol, and analyzed for the primary outcome. <a href="#">Describe protocol deviations from study as planned, together with reasons.</a>	
Recruitment	14	<a href="#">Dates defining the periods of recruitment and follow-up.</a>	
Baseline data	15	<a href="#">Baseline demographic and clinical characteristics of each group.</a>	
Numbers analyzed	16	<a href="#">Number of participants (denominator) in each group included in each analysis and whether the analysis was by "intention-to-treat"</a> . State the results in absolute numbers when feasible (e.g., 10/20, not 50%).	
Outcomes and estimation	17	<a href="#">For each primary and secondary outcome, a summary of results for each group, and the estimated effect size and its precision</a> (e.g., 95% confidence interval).	
Ancillary analyses	18	<a href="#">Address multiplicity by reporting any other analyses performed</a> , including subgroup analyses and adjusted analyses, indicating those pre-specified and those exploratory.	
Adverse events	19	<a href="#">All important adverse events or side effects in each intervention group.</a>	
DISCUSSION Interpretation	20	<a href="#">Interpretation of the results</a> , taking into account study hypotheses, sources of potential bias or imprecision and the dangers associated with multiplicity of analyses and outcomes.	
Generalizability	21	<a href="#">Generalizability (external validity) of the trial findings.</a>	
Overall evidence	22	<a href="#">General interpretation of the results in the context of current evidence.</a>	

Revised template of the CONSORT diagram showing the flow of participants through each stage of a randomized trial.

20 IPD Invasive pneumococcal disease  
21

22 **What's known on this subject:**

23 Premature infants have a higher risk of invasive pneumococcal disease and are more likely to  
24 have lower vaccine responses compared to term infants. The optimal primary schedule to  
25 generate protective concentrations of pneumococcal antibodies in preterm infants is  
26 unknown.  
27

28 **What this study adds:**

29 This 13-valent pneumococcal conjugate vaccine schedule RCT in preterm infants  
30 demonstrated that fewer priming doses resulted in higher post-booster, but lower post-  
31 primary IgG concentrations. The optimum schedule for preterm infants depends when they  
32 are most at risk of invasive disease.

**Contributors' Statement Page:**

Dr A Kent coordinated the study, performed statistical analysis and drafted the initial manuscript.

Dr S Ladhani assisted with the design of the study, coordination of the study, critically reviewed the manuscript and approved the final manuscript as submitted.

Dr N Andrews approved the data collection tools, performed the statistically analysis, critically reviewed the manuscript and approved the final manuscript as submitted.

Dr T Scorrer, Prof A Pollard, Dr P Clarke, Dr S Hughes, Dr C Heal, Dr E Menson, Dr J Chang, Dr P Satodia, Dr A C Collinson, Dr N Pritchard and Dr S Faust were members of the trial steering committee, recruited participants and were responsible for data collection and study procedures at their sites. They critically reviewed the manuscript and approved the final manuscript as submitted.

Prof D Goldblatt supervised the analysis of all laboratory samples, critically reviewed the manuscript and approved the final manuscript as submitted.

Prof E Miller and Prof P T Heath were responsible for the concept and design of the study and the overall supervision of all aspects of the clinical trial. They critically reviewed the manuscript and approved the final manuscript as submitted.

## Abstract

### Background

Premature infants have a higher risk of invasive pneumococcal disease and are more likely to have lower vaccine responses compared to term infants. Increasingly, immunization schedules are including a reduced, 2-dose, pneumococcal conjugate vaccine (PCV) priming schedule.

We aimed to assess the immunogenicity of 3 commonly used PCV13 priming schedules in premature infants, and their response to a 12-month booster dose.

### Methods

Premature infants (<35 weeks gestation) were randomized to receive PCV13 at 2 and 4 months (reduced schedule); 2, 3 and 4 months (accelerated schedule); or 2, 4 and 6 months (extended schedule). All infants received a 12-month PCV13 booster. Serotype-specific pneumococcal immunoglobulin G (IgG) for PCV13 serotypes were measured by ELISA 1 month after primary and booster vaccinations.

### Results

A total of 210 infants (median birth gestation 29<sup>+6</sup> weeks, range 23<sup>+2</sup>-34<sup>+6</sup>) were included. Following primary vaccination, 75% (95% CI 62-85), 88% (95% CI 76-95) and 97% (95% CI 87-99) of participants had protective antibody concentrations for at least half the PCV13 serotypes for the reduced, accelerated and extended schedules respectively. Following booster vaccination, participants receiving the extended schedule had significantly lower ( $p<0.05$ ) geometric mean concentrations compared with reduced (for 9/13 serotypes) and accelerated schedules (for 4/13 serotypes).

### Conclusions and Relevance

Fewer priming doses of PCV13 resulted in lower post-primary concentrations but higher post-booster IgG concentrations. ~~but lower post-primary concentrations. than an extended schedule.~~ The optimum vaccine schedule for preterm infants will therefore depend on ~~the setting and~~ when they are most at risk of invasive pneumococcal disease.

## Introduction

Premature infants are at increased risk of vaccine preventable diseases, including a two-fold risk of invasive pneumococcal disease (IPD) compared to term infants.[1–3]

In most industrialised countries with established pneumococcal immunization programmes, the 13-valent pneumococcal conjugate vaccine (PCV13) has superseded the 7-valent PCV and has been shown to be highly immunogenic in term infants.[4–6]

The immunogenicity of PCV13 in premature infants receiving a 2-3-4 and 12-month schedule was only recently reported and showed lower immunoglobulin G (IgG) concentrations for 8 serotypes after both primary and booster doses compared to term infants.[7] This lower immunogenicity is consistent with previous PCV7 studies [8–10] ~~after both primary and booster immunization~~ and is concerning because premature infants are also less likely to benefit from the protective maternal antibodies ~~that are passively~~ transferred during late pregnancy.

Additionally, national immunization programmes are increasingly including reduced (2) dose priming schedules ~~due to the diminishing risk of disease in highly vaccinated populations and an increasing number of vaccines to accommodate.~~ [11,12] These schedules are immunogenic in term infants and, with some vaccines, may even improve B cell memory and booster responses.[13–16] However, little is known about the immunogenicity of fewer primary doses in premature infants.

This randomized, controlled trial aimed to assess the immunogenicity of reduced, accelerated (intended to provide maximum early protection) and extended (doses administered over a longer period) PCV13 priming schedules in premature infants after completion of the primary series and after a 12-month booster.

## Patients and Methods

### Participants and recruitment

Premature infants were enrolled in a phase IV open-label randomized controlled trial from 12 UK centres between May 2012 and May 2013. Potentially eligible infants were identified by the clinical teams and parents were provided with information ~~on the trial~~ by the research teams. Infants were eligible for inclusion if they had a birth gestation less than 35<sup>+0</sup> weeks, had no contra-indications for vaccination as defined by Department of Health guidelines[17] and were between 7 and 12 weeks of age. Additionally, infants should not have received any other vaccinations (with the exceptions of BCG and hepatitis B). Information on the participants' past medical, medication and vaccination history was collected from the medical records using a standardised case report form.

Written informed consent was obtained from parents prior to enrolment. The study was approved by the East of England – Essex research ethics committee (REC reference 07/HO301.11) and registered on the EudraCT clinical trial database (2007-007535-23).

### Vaccination

Infants were randomly assigned (1:1:1) to receive PCV13 (Prevenar13; Pfizer, New York) at 2 and 4 months of age (reduced schedule - Group 1), at 2, 3 and 4 months of age (accelerated schedule - Group 2) or at 2, 4 and 6 months of age (extended schedule - Group 3)(supplementary table 1). A booster dose of PCV13 was administered to all infants at 12 months of age. Additionally, all participants received a combined diphtheria, tetanus, acellular pertussis, *Haemophilus influenzae* type b and inactivated polio vaccine (Pediace1; Sanofi Pasteur MSD, Lyon, France) at 2, 3 and 4 months old, meningococcal C-CRM<sub>197</sub> vaccine (Menjugate; Novartis Vaccines, Siena, Italy) at 3 and 4 months of age and a combined measles, mumps and rubella vaccine (Priorix; GlaxoSmithKline Biologicals,

1  
2  
3  
4  
5  
6  
7 Rixensart, Belgium) and Hib-MenC-TT conjugate vaccine (Menitorix, GlaxoSmithKline  
8 Biologicals, Rixensart, Belgium) at 12 months of age (supplementary table 1). Participants  
9 were vaccinated in hospital if still receiving inpatient care. All vaccines were administered  
10 intramuscularly.  
11

12  
13  
14 Computerised block randomization was stratified by centre and gestation (<30 or ≥30 weeks  
15 gestation) and each centre was allocated blocks of sequential numbers (block size 18).  
16

17  
18 Following consent the subject was allocated the next available study number for that centre  
19 and gestational age cohort, and the appropriate sealed envelope containing the group  
20 allocation opened. The study was not blinded to parents or clinical personnel.  
21  
22  
23

#### 24 25 26 **Blood sampling and serological methods**

27  
28 Up to 3 mL of whole blood was obtained from each participant prior to the first vaccination  
29 (baseline), 1 month following primary vaccination (at age 5 months for Groups 1 and 2  
30 participants and at age 7 months for Group 3 participants), prior to and 1 month after booster  
31 vaccination (12 and 13 months respectively) (supplementary table 1).  
32  
33

34  
35 Serological analysis was performed at the World Health Organisation reference laboratory for  
36 pneumococcal serology, Institute of Child Health, London. Following extraction from whole  
37 blood, sera were stored at -70°C prior to assay for pneumococcal serotype-specific  
38 immunoglobulin G (IgG) concentrations for the PCV13 pneumococcal serotypes by enzyme-  
39 linked immunosorbent assay (ELISA) as previously described.[18] The lower limit of assay  
40 quantification was 0.15 µg/mL and IgG concentrations ≥0.35 µg/ml were considered  
41

### 17 18 **Statistical analysis**

19  
20 The primary objectives were to assess IgG geometric mean concentrations (GMCs) and the  
21 proportion of infants with protective serotype-specific antibody concentrations for PCV13  
22 serotypes at 1 month after completion of the primary vaccination course, according to the 3  
23 schedules. The main secondary objectives were to assess differences in serotype-specific IgG  
24 GMC and seroprotection rates between schedules prior to and following booster vaccination  
25 at 12 months of age; and to quantify the percentage of children experiencing fever, local  
26 reactions and non-febrile systemic reactions within 7 days following each vaccine dose.  
27  
28  
29

30  
31 Pre-trial sample size calculations estimated a minimum of 60 infants in each group to detect  
32 at least a 2 fold difference between groups after primary immunization, with 80% power and  
33 5% significance. Based on published data, the standard deviation of IgG responses was  
34 estimated be 0.6 log<sub>10</sub> units.[20] To allow for drop out of subjects over the course of the  
35 study and the challenges of obtaining blood samples from very premature infants, we aimed  
36 to recruit 210 infants.  
37  
38  
39

40  
41 Data were analyzed using a modified intention to treat analysis including all infants who  
42 received a dose of PCV13 and from whom at least one post-vaccination blood sample was  
43 obtained. GMCs and 95% confidence intervals (CI) were calculated for each sampling time  
44 point, along with the proportion of infants achieving protective antibody concentrations and

7 binominal CI. Results below the lower limit of quantification (LLQ) were taken to be half  
8 the LLQ for computational purposes.

9  
10 Statistical comparison of antibody concentrations and the proportion of participants with  
11 protective concentrations or AEs between the 3 trial arms were performed using the Student's  
12 t-test and the  $\chi^2$ -test or Fisher's exact test, as appropriate. Statistical significance was defined  
13 as  $p < 0.05$ . To facilitate comparisons we have analysed schedules based on the proportions  
14 achieving adequate protection for at least half of the serotypes. The number of serotypes with  
15 protective concentrations per participant were compared using the non-parametric Kruskal–  
16 Wallis one-way analysis of variance test.  
17  
18  
19  
20  
21  
22  
23

24 Logistic regression was used to examine the effect of gestation, the receipt of antenatal or  
25 postnatal steroids, blood transfusion, BCG vaccination, early post-vaccination paracetamol  
26 and the presence of chronic lung disease (CLD, defined as requiring oxygen or respiratory  
27 support at 28 days of age) on seroprotection. Analysis was adjusted for gestation. For post-  
28 primary vaccination results multivariable linear regression using log-transformed values was  
29 performed (adjusting for group and gestation). Linear regression was not performed on  
30 baseline IgG concentrations due to the large number of results below the LLQ.

## Results

A total of 210 infants were recruited. 199 participants (94.7%) completed the primary phase (primary endpoint) and 194 (92.4%) completed the entire study (Figure 1). 2 participants died of causes unrelated to the trial. The majority of infants who did not meet the inclusion criteria were outside the study age range or were too unstable for vaccination. A second group of infants was excluded for logistical reasons - many were transferred to their local neonatal unit prior to their first vaccination (Figure 1).

The characteristics of randomized infants were similar between groups (Table 1) with a median birth gestation of 29<sup>+6</sup> (range, 23<sup>+2</sup>-34<sup>+6</sup>) weeks and median birth weight of 1388g (range: 450-3390g). 112 vaccinations were administered to hospitalized participants.

### Primary vaccination

At baseline participants had very low antibody concentrations for all pneumococcal serotypes (Table 2, supplementary table 2). The highest IgG GMCs (for all participants) were seen for serotypes 14 (0.26 µg/mL) and 19A (0.19 µg/mL).

Following the primary vaccination course, substantial increases in antibody concentrations were seen for all serotypes and all groups. There was considerable variation between serotypes with IgG GMCs ranging from 0.16 µg/mL for serotype 6B (reduced schedule) to 8.49 µg/mL for serotype 14 (extended schedule) (Figure 2; Supplementary Table 3).

The primary schedule had a significant impact on vaccine immunogenicity. Lack of seroprotection for more than half the PCV13 serotypes was seen in 25%, 12% and 3% of participants receiving the reduced, accelerated and extended schedules respectively (p<0.001, supplementary figure 1 and supplementary table 4).

1  
2  
3  
4  
5  
6  
7 Participants receiving the extended schedule had higher IgG GMCs compared with the  
8 reduced schedule for 11 serotypes and accelerated schedule for 7 serotypes. The accelerated  
9 schedule was superior to the reduced schedule for 4 serotypes (Figure 2, Table 2;  
10 Supplementary table 3).  
11  
12  
13

### 14 15 16 **Booster vaccination**

17  
18 At 12 months of age, waning of pneumococcal antibody concentrations was evident with low  
19 rates of seroprotection against individual serotypes (Table 3; Supplementary table 5).  
20  
21 Antibody concentrations remained significantly higher in those who had received the  
22 extended schedule compared with reduced (for 10 serotypes) or accelerated schedules (for 11  
23 serotypes), the accelerated schedule was superior to the reduced schedule for one serotype  
24 only.  
25  
26  
27  
28  
29  
30

31  
32 Following booster vaccination a high proportion of infants achieved protective concentrations  
33 (Table 3). As at previous time points, significant variation in antibody concentrations  
34 between serotypes and groups was apparent (Figure 3). In contrast to post-primary  
35 vaccination responses, participants receiving the extended schedule had lower GMCs  
36 compared with the reduced (for 9 serotypes) and accelerated schedules (for 4 serotypes). The  
37 accelerated schedule was inferior to the reduced schedule for one serotype (19A)  
38 (supplementary table 6). Infants who received the extended schedule had lower fold  
39 increases in concentrations following booster vaccination than the other groups  
40 (supplementary figure 2).

47  
48

### 49 50 51 **Predictors of antibody concentrations**

1  
2  
3  
4  
5  
6  
7 Increased odds of seroprotection at 2 months of age were seen with each week of increased  
8 gestation for 4 serotypes: 6A (OR 1.34, 95% CI 1.12-1.60; p=0.001), 14 (OR 1.25, 95% CI  
9 1.12-1.41; p<0.001), 19A (OR 1.27, 95% CI 1.12-1.45; p<0.001) and 19F (OR 1.29, 95% CI  
10 1.09-1.52; p=0.003). Later gestation was associated with an increase in post primary  
11 vaccination IgG concentrations for 3 serotypes: 1 (6% increase per week, 95% CI 0.9-12;  
12 p=0.021), 3 (8% increase per week, 95% CI 4-14, p<0.001) and 7F (8% increase per week,  
13 95% CI 3-13; p=0.002).

14  
15  
16  
17  
18  
19  
20  
21 Receipt of antenatal steroids was associated with decreased odds of seroprotection at 2  
22 months for 4 serotypes: 5 (OR 0.09, 95% CI 0.01-0.83; p=0.033), 6A (OR 0.26, 95% CI 0.10-  
23 0.69; p=0.006), 19A (OR 0.19, 95% CI 0.08-0.45; p<0.001) and 23F (OR 0.23, 95% CI 0.06-  
24 0.80, p=0.021). Additionally, post-primary vaccination serotype-specific IgG GMCs for  
25 serotypes 1, 4 and 9V were reduced in infants who had been exposed to antenatal steroids.  
26 At no time-points were antenatal steroids associated with higher antibody concentrations.  
27  
28  
29  
30  
31  
32  
33  
34  
35

36 Pre- or post-primary protective concentrations were not associated with any other factors in  
37 regression analysis. An insufficient number of infants (14) received postnatal steroids to  
38 analyse any effect. Serotype-specific antibody concentrations after the 12-month PCV13  
39 booster were affected by priming schedule and pre-existing antibody levels only.  
40  
41  
42  
43  
44

#### 45 **Safety and adverse events**

46 There were no significant differences in the frequency or severity of local and systemic AEs  
47 between vaccination schedules at any time-point. Altogether 77 serious adverse events  
48 (SAEs) were reported (including the 2 deaths). SAEs were predominantly acute respiratory  
49 infections. There was 1 possibly related (suspected) unexpected serious adverse reaction

11

## 12 13 14 **Discussion**

15  
16 This is the first study to compare different PCV13 schedules in premature infants and  
17 demonstrates the need for early and effective immunization strategies for this vulnerable  
18 group, given their very low pre-immunization antibody concentrations. Our results indicate  
19 that most preterm infants can achieve seroprotective antibody concentrations for the  
20 serotypes in PCV13 regardless of the primary schedule administered, especially after the 12-  
21 month booster, but the magnitude of their immunological response is dependent on the  
22 primary schedule they receive.  
23  
24  
25  
26  
27  
28  
29

30  
31 Serotype-specific responses varied, with lower IgG GMCs achieved for serotypes 3, 5 and 6B  
32 after the primary course and for serotypes 3, 9V and 18C after the booster dose; these  
33 findings are consistent with those observed in term infants.[4,21] However, when compared  
34 with previous term (PCV13) and preterm (PCV7) studies, antibody concentrations after  
35 primary and booster vaccination are lower overall, resulting in lower seroprotection following  
36 primary vaccination.[4,5,8,9,2022]  
37  
38  
39  
40  
41  
42

Field Code Changed

43  
44  
45 Similarly, compared with the recent PCV13 preterm study[7], lower IgG GMCs and  
46 seroprotection rates were seen for all serotypes. These differences may be due to the  
47 different laboratory testing methodology for serotype-specific antibody concentrations, but  
48 potential biological explanations include interactions with concurrently administered  
49 vaccines, the younger gestation of our cohort or our broad inclusion criteria encompassing  
50

7 infants with complex medical problems – representative of the preterm population.

8 Additionally, Martinon-Torres *et al.* did not report baseline IgG concentrations which may  
9 differ between countries and impact on post-vaccination concentrations.[7]  
10  
11

12  
13  
14 When comparing schedules within our cohort, the most striking finding was the contrasting  
15 immunogenicity of the 3 schedules at different time points, with the reduced dose schedule  
16 generating inferior antibody concentrations after the primary course but superior antibody  
17 concentrations after the booster dose. The higher post-primary IgG GMCs following 3 doses  
18 (compared with 2 doses) is consistent with two meta-analyses of primary schedules in term  
19 infants.[23,24] Of the 3-dose schedules, higher antibody concentrations were seen in  
20 premature infants receiving the extended schedule. This was not observed in the meta-  
21 analyses of term infant responses but an older age at final vaccination may be more important  
22 in premature infants as it will allow further maturation of their immune system.[25,26]  
23  
24 However, this needs to be set against the optimal age at which protection is required in this  
25 population. Several studies have indicated an increased susceptibility of IPD in babies born  
26 prematurely when compared with term infants; this risk appears maximal in the first 6 months  
27 of life.[1–3]  
28  
29

30  
31  
32 The differences in response to the booster dose was unexpected as the type of priming  
33 schedule has not been consistently shown to affect the generation of immunological memory  
34 and PCV booster vaccine responses in term infants.[23,27] The improved post-booster  
35 immunogenicity of fewer priming doses is well described for meningococcal C conjugate  
36 vaccines and is thought to be due to lower total antigen exposure favouring differentiation of  
37 B lymphoblasts into memory B cells instead of antibody-generating plasma cells.[14,15] In  
38 pneumococcal conjugate vaccines, a study of Fijian infants receiving one PCV7 priming dose

1  
2  
3  
4  
5  
6  
7 followed by the 23-valent pneumococcal polysaccharide vaccine (PPV23) at 12 months had  
8 higher IgG GMC for serotypes 4, 9V, 19F compared with those who had been primed with  
9 two or three PCV7 doses.[13] Similarly, infants receiving a lower antigen-containing  
10 investigational tetravalent PCV for priming had higher booster responses than those who had  
11 received the higher antigen-containing preparation.[28] However, it should be noted that a  
12 statistically significant difference between the reduced and accelerated schedule groups was  
13 observed for only one serotype.  
14  
15  
16  
17  
18  
19

20  
21 Despite seroprotective concentrations, infants who had received the extended schedule had  
22 lower fold increases in antibody concentrations following booster vaccination than those  
23 receiving either the reduced dose or accelerated schedules suggesting that the higher pre-  
24 booster antibody concentrations at 12 months may have interfered with booster responses.  
25 This effect has been observed following booster doses for other vaccines and several  
26 hypotheses have been proposed including the formation of immune complexes consisting of  
27 pre-existing antibody and vaccine antigen resulting in less available vaccine antigen, and B  
28 cell receptor mediated negative feedback mechanisms, analogous to those described for high  
29 maternal antibody concentrations impairing primary vaccine responses.[29–33]  
30 Within our cohort of premature infants, increasing birth gestation was associated with  
31 increased immunogenicity. This has previously been described for other vaccines and  
32 reflects deficiencies in both the innate and adaptive immune systems in these more premature  
33 infants.

### Limitations

The study had some potential limitations. The different ages of infants at blood sampling between the groups must be considered when comparing primary schedules; the antibody

1  
2  
3  
4  
5  
6 concentrations at 7 months for babies in Groups 1 and 2 are not known. It is possible, that  
7 infants in those groups may have had a rise in their antibody concentrations between their 5  
8 month sample and 7 months of age due to natural exposure.[40] However, a recent study  
9 comparing schedules in term infants which sampled some infants at both 5 and 8 months did  
10 not find a rise in antibodies between these ages.[27] We also did not measure antibody  
11 concentrations beyond 13 months of age.  
12  
13

14  
15  
16 As the objectives of this study were to look at schedule differences within the premature  
17 population we did not include a term comparator group, however lower antibody  
18 concentrations were seen in our cohort when compared with a recent cohort of term infants in  
19 the UK who received a reduced dose schedule, which was analyzed in the same  
20 laboratory.[22]  
21  
22

23  
24 Additionally, we did not include any assessment of functional activity of the antibodies  
25 detected. Opsonophagocytic antibody titres may have allowed us to assess the potential  
26 clinical impact of schedule differences in more detail and should be considered in future  
27 studies. A previous meta-analysis of primary PCV schedules in term infants has shown a  
28 good relationship between ELISA measured IgG concentrations and opsonophagocytic  
29 antibody titres, however an analysis of serotype-specific OPA values did not find a consistent  
30 protective OPA titre across all vaccine serotypes.[~~22,39~~24,41]

### 43 Conclusion

44  
45 PCV13 is well tolerated in premature infants ~~but immunogenicity is related to the~~ Different  
46 priming schedule and different schedules offer better protection result in higher IgG concentrations  
47 at different ages. The choice of schedule should therefore reflect the local epidemiology of IPD as the  
48 optimal schedule for times during the first 13 months of life. We believe that such data will be  
49 of benefit to those planning or providing pneumococcal vaccines to preterm infants ~~depends~~

~~on when they are most at risk. In countries with little IPD in the first year of life a reduced dose primary schedule may be preferred due to higher post-booster antibody concentrations, however the duration of protection remains unknown. and will enable them to consider this in the context of their own immunization programmes and epidemiological situations.~~

Change the main title (both in your paper and in online Step 1) to: Schedules for Pneumococcal Vaccination of Preterm Infants: An RCT	Altered text: Schedules for Pneumococcal Vaccination of Preterm Infants: An RCT	Title	
Change the short title (both in your paper and in online Step 1) to: Schedules for Pneumococcal Vaccination	Altered text: Schedules for Pneumococcal Vaccination of Preterms	Short title	
Please use our standard headings in the abstract, as shown in the author guidelines	Amended as suggested	Abstract	
What this study adds. Instead of 'fewer priming doses' should state 'a reduce or accelerated schedule'. Does the last sentence here add anything?	Thank you. We have re-phrased as suggested: "This 13-valent pneumococcal conjugate vaccine schedule RCT in preterm infants demonstrated that a reduced primary schedule resulted in higher post-booster, but lower post-primary IgG concentrations. The optimum schedule for preterm infants depends on when they are most at risk of invasive disease."	Abstract

	these vaccines are immunogenic in preterm infants but also that the schedule appear to have an effect. We do not believe it implies equal protection between schedules		
Pg 16 line43. The discussion of the relation of priming doses to boosting should be qualified by noting that only one significant difference was observed between the reduced and accelerated schedules after boosting.	We have added the following sentence to emphasize this point 'However, it should be noted that a statistically significant difference between the reduced and accelerated schedule groups was observed for only one serotype.'	Page 17, line 12	
Pg 18 limitations- should also include that no followup testing was done beyond one month past the booster.	Thank you, we have added 'We also did not measure antibody concentrations beyond 13 months of age.'	Page 18, line 12	
The principle objective of the study was stated to be the comparison of protection after the primary series, with the comparison of post-booster results as a secondary objective. This conclusion appears to advocate for the use of the reduced schedule, which seems difficult to support given the findings. All schedules produced adequate post-booster levels; the benefits of the higher booster results from the reduced schedule are thus somewhat speculative without further research. In addition I doubt that many or most NIPs are aware of local IPD epidemiology or of the potential for future outbreaks- and if overall population PCV13 level is factored in, I doubt that there is true differentiation of IPD epidemiology for premature infants on a local level. The authors should reconsider this conclusion statement.	Thank you for your comments. We have tried to avoid supporting one schedule over another as many factors need to be taken into account when implementing a schedule. We have therefore modified the wording so that we are not appearing to advocate one schedule over another. "PCV13 is well tolerated in premature infants but different priming schedules result in higher IgG concentrations at different times during the first 13 months of life. We believe that such data will be of benefit to those planning or providing pneumococcal vaccines to preterm infants and will enable them to consider this in the context of their own immunization programmes and epidemiological situations".	Page 18, line 50	
Supplementary Table 1: Please check the Age row for typos.	Thank you – amended age at visit 3 to 4 months		

**Instructions:**

Please use this table format to answer the questions posed by the editors and reviewers of your paper. Copy and paste the editor/reviewer’s question in the “Comments” column and your answer to that question in the corresponding “Response” column. Be sure to ALSO paste the corrected text along with your response. For minor copyediting changes such as spelling and grammar corrections, you may simply state that the error was corrected, without pasting the altered text.

For clarity, use one row per question. Make sure to list the page and line reference where your change can be found. If no change was made, please make sure to note that in your response in addition to your reasoning. You may delete the sample row and insert rows to this table as needed.
