ABSTRACT

The relationship between energy use and height is examined for a sample of 611 office buildings in England and Wales using actual annual metered consumption of electricity and fossil fuels. The buildings are of different ages; they have different construction characteristics and methods of heating and ventilation; and they include both public and commercial offices. When rising from five storeys and below to 21 storeys and above, the mean intensity of electricity and fossil fuel use increases by 137% and 42% respectively, and mean carbon emissions are more than doubled. A multivariate regression model is used to interpret the contributions of building characteristics and other factors to this result. Air-conditioning is important, but a trend of increased energy use with height is also found in naturally ventilated buildings. Newer buildings are not in general more efficient: the intensity of electricity use is greater in offices built in recent decades, without a compensating decrease in fossil fuel use. The evidence suggests it is likely – although not proven – that much of the increase in energy use with height is due to the greater exposure of taller buildings to lower temperatures, stronger winds and more solar gains.

Introduction

Taking the domestic and non-domestic sectors together, the average annual turnover of the UK building stock is only 1% (Jones, Patterson, & Lannon, 2007). Consequently, significant improvements are required across both new and existing buildings to meet long-term national emissions-reduction targets. In order to ensure that any decisions about changes to the existing stock or the design of new buildings are made effectively, an understanding is required about the relationships between building characteristics and energy use.

Historically, global trends in high-rise construction have reflected changing technologies, planning policies, architectural interests and broader societal concerns (Oldfield, Trabucco, & Wood, 2009). In recent years, the UK has been building taller. In 2015, approximately one-third of the UK's 100 tallest buildings had been completed in the previous five years; by 2020, this trend is expected to accelerate further (Skyscraper Center; <http://www.skyscrapercenter.com/>). However, despite perceptions that tall buildings are necessary to achieve high urban densities, research

has shown that this is not the case. It is often possible to achieve the same densities as tall, freestanding towers with lower-rise buildings designed as slabs, terraces or courtyards (Steadman, 2014). Since the turnover of buildings is so slow, and the need for high-rise is debatable, it is particularly important to examine the impact of built form design choices on energy performance.

This paper examines the energy consumption of offices in England and Wales, using information for 611 buildings, collected from three sources of disaggregate data: the Display Energy Certificate (DEC) scheme, the Better Buildings Partnership (BBP) and the London Mayor's Energy Challenge (EC) databases. The analysis focuses on the impact of building height on electricity and fossil fuel use, as well as emissions.

Energy, height and the external environment of buildings

The structural design of high-rise buildings is typically more complex than low-rise buildings due to the

increased load effects associated with height (Tamošaitienė & Gaudutis, 2013). Consequently, embodied energy intensity increases substantially as buildings get taller (Resch, Bohne, Kvamsdal, & Lohne, 2016; Treloar, Fay, Ilozor, & Love, 2001), although this 'height premium' can be partly mitigated through design and material choices (Ali & Moon, 2007; Chau, Hui, Ng, & Powell, 2012; Foraboschi, Mercanzin, & Trabucco, 2014). Typically, however, embodied energy accounts for only 10–20% of the overall lifecycle of buildings compared with 80–90% associated with operational energy (Ramesh, Prakash, & Shukla, 2010).

Energy consumption in the operation of buildings is determined by a large number of variables, including distinct architectural and engineering design choices, as well as broader factors such as occupancy behaviour and the external environment. Analyzing the drivers of building performance, Baker and Steemers (1994) suggest that building design, including height, can account for a 2.5 times variation in energy use, while the systems and occupancy behaviour each account for a 2.0 times variation. This analysis was expanded to consider urban geometry, which was found to account for approximately a 10% variation in energy use (Ratti, Baker, & Steemers, 2005).

Other things being equal, the primary direct impact of a building's height on its energy consumption is through interactions with the external environment.¹ Climate changes with altitude, affecting thermal transfer and infiltration rates. For example, external air temperature and wind speed fall and rise with altitude respectively, although the magnitude of change varies with local conditions (CIBSE, 2006). Access to daylight and solar gains, meanwhile, is determined by the height and location of a building relative to its surroundings. While the effect of each separate factor may be straightforward to estimate, the net impact on energy consumption for any specific building will depend on variables including the installed systems, occupancy behaviour and exposed thermal mass. For example, increased daylight availability will only reduce a building's demand for artificial lighting if the controls are somehow linked to daylight, and there are no adverse effects that encourage occupants to close blinds, such as excessive glare, solar gains or privacy issues.

Many of the studies that consider building height use thermal modelling to estimate the performance of theoretical built forms. Analyzing simple forms introduces the complication that the number of storeys, total floor area and area per floor are interlinked. Parasonis, Keizikas, and Kalibatiene (2012) and Hemsath and Bandhosseini (2015) show that, maintaining total floor area, building height correlates positively with heat loss and modelled residential energy use, largely driven by resulting changes in overall compactness. Significantly, height was found to

have a greater impact on residential energy use than construction materials, depending on the climate (Hemsath & Bandhosseini, 2015). A small number of studies model the energy performance for case study buildings. Ellis and Torcellini (2005) showed that total heating and cooling energy use in a simple rectangular office skyscraper in Manhattan increases between the lowest and highest floors. The net increase in energy consumption was relatively small (approximately 3% rise between the bottom and top storeys). However, by repeating the analysis multiple times with different model settings, they illustrated that the driving force for this trend was the change in overshadowing from surrounding buildings, suggesting that a key factor is the relative form of a building compared with its surroundings. This is echoed in a case study in Singapore that estimated that 4.7% of building cooling demand was associated with the relative height of the surrounding buildings (Wong et al., 2011). Similarly, Steemers (2003) notes that in order to minimize energy demand, glazing ratios should reduce considerably between lower and upper floors, reflecting the variation in local obstructions with height. For London, mean glazing ratios of 38% and 25% are proposed for ground level and at 30 m respectively.

While building simulation enables controlled tests to be undertaken, a comparison with empirical data highlights the difficulty of accounting for factors such as occupancy behaviour (Wright, 2008). Furthermore, assumptions about building characteristics may not be straightforward. For example, a survey of offices in the US and the UK found no correlation between airtightness and building age or materials, but found that taller buildings tended to have lower infiltration rates (Emmerich & Persily, 1998). The need for actual energy and building data to form the basis of research into the built environment, rather than relying solely on modelled energy demand and theoretical building characteristics, is urged by Hamilton et al. (2013) who propose a greater focus on empirical methods such as 'energy epidemiology'. They highlight the need for large-scale (preferably population-level) analyses to be carried out where possible, and for smaller studies to be undertaken within the context of the overall population. Moreover Gonçalves and Bode (2011) note that the need to analyze metered energy data is especially pertinent for tall buildings, where energy reductions can be particularly challenging to achieve.

In recent years, a small number of large-scale studies of disaggregate energy data have been undertaken using publicly available data for the UK (Armitage, Godoy-Shimizu, Steemers, & Chenvidyakarn, 2015; Godoy-Shimizu, Armitage, Steemers, & Chenvidyakarn, 2011; Hong & Steadman, 2013) and the US (Yalcintas & Aytun Ozturk, 2007). A recent survey, examining the

energy data of schools in England, found no significant variation in energy with height (Hong, Paterson, Mumovic, & Steadman, 2014). However, this likely reflects the building type, which is predominantly naturally ventilated and very low-rise (Tian & Choudhary, 2012). In contrast, an analysis of aggregate energy use in London found that domestic gas consumption was higher in areas marked by tall buildings when accounting for other influencing factors (Hamilton et al., 2017). No equivalent variation in domestic electricity use was found. Elsewhere, a study examining the data from a survey of 20 all-electric air-conditioned offices in Hong Kong reveals a 43% increase in mean electricity use intensity between buildings below 11 storeys and those above 20 storeys (Lam, Chan, Tsang, & Li, 2004).² Electrical equipment and heating, ventilation and air-conditioning (HVAC) accounted for the largest absolute increase in mean intensity, rising by 43 and 40 kWh/m² respectively. Interestingly, mean lighting intensity increased by 20% between the shortest and tallest buildings, despite a corresponding rise in glazing level and reduction in overshadowing from surrounding buildings.

Taken as a whole, the literature highlights the need for further large-scale, empirical examination of the relationship between building height and energy use. While the influence on embodied energy is well understood, relatively few studies have examined the impact of height on operational energy. A number of studies have found a positive correlation between energy consumption and height. However, many of these rely on modelled, rather than actual, energy data and the empirical studies that do exist typically consider small numbers of buildings. The work reported here is new in considering energy and height, using actual metered energy data, for a large number of buildings.

Structure of this paper

This paper examines the performance of several hundred offices in England and Wales, using disaggregate energy data gathered from three sources. The data were combined with other pre-existing information, alongside the results of a desktop survey undertaken by the authors. This combined data set has been analyzed to evaluate how energy use varies with building height.

The paper is structured as follows. The next section summarizes data that were collected and outlines the processing undertaken to produce a unified buildings database. Next, the overall energy performance of the sample is assessed, including the variation with height, and a generalized linear modelling (GLM) is produced. Finally, the results are discussed, with proposals for further work.

Methods

The key underlying requirement for statistical building studies of this nature is actual, metered disaggregate energy-use data, available for a large sample of buildings. A small number of recent studies have analyzed the performance of the UK stock in this way, using energy data from DEC's (Godoy-Shimizu et al., 2011; Hong et al., 2014). The DEC database is a collection of energy records gathered since 2008 mostly for public buildings in England and Wales, and originally introduced to improve public understanding about energy use in the building stock (Department of Energy and Climate Change (DECC), 2013). Aside from unavoidable factors such as human error, using data from a single source ensures that the collection and processing of the underlying data remains consistent. However, it also means that the analysis will reflect any biases within the original sample. For example, it has been found that public sector offices have different energy profiles compared with private offices (Department for Business, Energy & Industrial Strategy (BEIS), 2016). Consequently, an examination of the DEC database, which is predominantly public, will not reflect the behaviour of the non-domestic stock as a whole. Naturally, the impact of any biases will depend on the area of study. For example, public buildings form a greater proportion of the overall stock and total floor area in education than in the office or retail sectors.

For this study, energy data were gathered from three separate sources; the DEC, the BBP and the London Mayor's EC databases. The BBP is a consortium of private sector property companies devoted to improving the performance of the commercial building stock. The Mayor's Energy Challenge was a competition to encourage improvements in London's buildings. It should be noted that while using these sources together may ensure that the analysis covers a wider range of buildings than any individual source, biases will still exist within the overall sample. For example, all three sources skew towards buildings with large floor areas. Again, the databases are each connected with energy saving initiatives. Therefore, the buildings within the sample may tend to be operated with a greater focus on energy performance than the overall office stock. The energy data were originally collected in the periods 2009–14, pre-2011 and 2010–14 for the BBP, DEC and EC respectively.

Within the UK, a single register of disaggregate built form data does not exist. Therefore, the energy data were combined with additional information about the physical and operational characteristics of the sample from several different sources. These can be grouped into two broad categories:

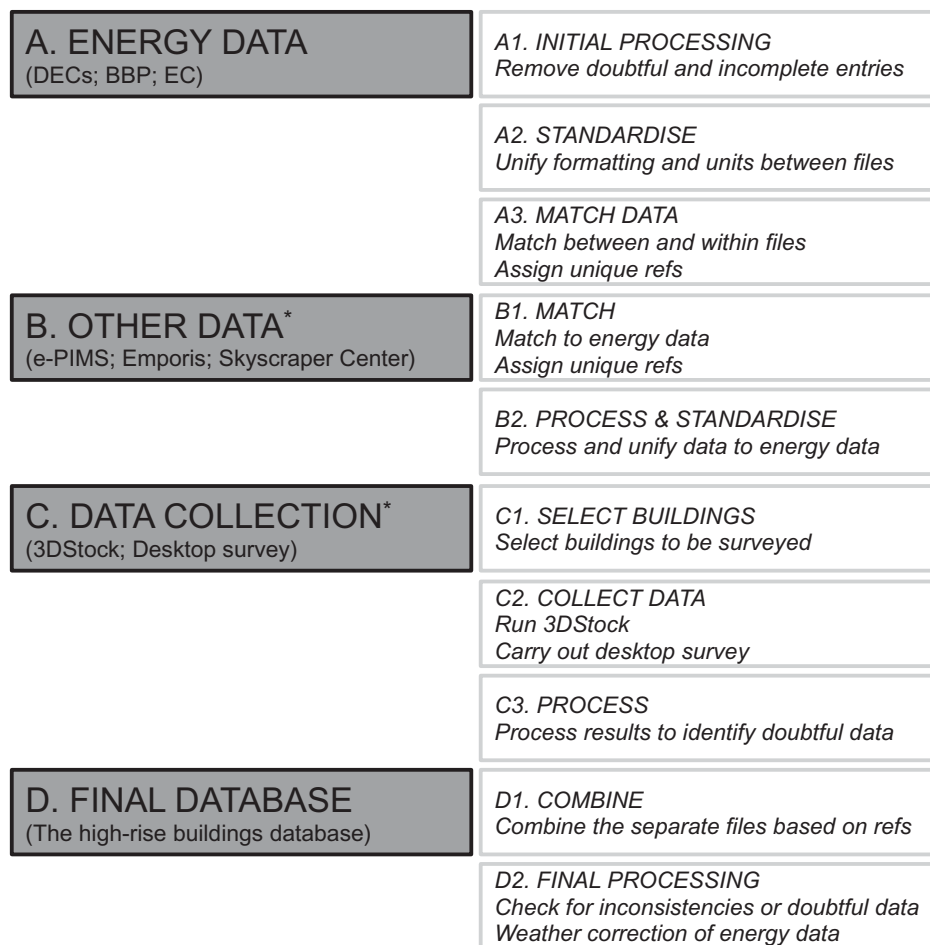

- **Existing data**
Information was gathered from three sources: the UK government's database of property information e-PIMS (<https://data.gov.uk/dataset/epims>), and two websites for tall buildings: Emporis (<https://www.emporis.com/>) and Skyscraper Center (<http://www.skyscrapercenter.com/>).
- **Additional data collection**
Further data were gathered by the authors through an implementation of 3DStock, a comprehensive model of the physical characteristics of buildings in England and Wales and the activities they house, generated using digital maps and property taxation data (Evans, Liddiard, & Steadman, 2017). A desktop survey was also carried out using imagery from Google Maps (<https://www.google.co.uk/maps>) and Bing Maps (<https://www.bing.com/maps>).

The information gathered from the different sources was originally collected at different times, and for different purposes. Consequently, considerable work was

necessary for checking, processing and combining the separate files. Figure 1 summarizes the approach taken. For full details, see the Appendix in the supplemental data online.

As the basis of the study, the energy data were processed first (step A in Figure 1). Addresses and construction ages were used to match entries associated with the same buildings. Next, each of the additional data sources was matched in turn (step B), and further data collection was undertaken (step C). Due to inconsistencies between the files, it was necessary to recheck old matches after each new source was added. For example, two entries might appear to cover separate buildings based on the addresses in the energy data. However, matching with the Skyscraper Center data might reveal that they are actually part of the same building. Finally, the different files were combined into a single database, using weather correction to adjust for differences in the collection periods for energy data (step D).

The final combined file consisted of information for 708 offices across England and Wales. However, the

Figure 1. Summary of the methodology used to produce the final database.

analysis that follows was carried out only on the 611 buildings for which the main heating fuel was identified as not being electricity. References to the ‘high-rise buildings data’ in this paper refer to this cleaned and combined final data set, and the analysis that follows was carried out on these data (or subsets of it) rather than on any of the original raw files. Table 1 summarizes the information within the final database. Variables in the original data that do not form part of this study are not listed. The desktop survey was designed as part of a broad study of built form and urban density. Consequently, several variables were included that were not used in this study. For full details of these, see Appendix in the supplemental data online.

Results and discussion

This section examines the energy performance of the buildings within the high-rise database. The analysis is presented in two parts:

- *Height and energy performance*

The overall relationship between height and energy use is summarized. Within the literature, different approaches exist to categorizing building height. Studies have used between 10 and 20 storeys as the ‘high-rise’ boundary. Furthermore, while some sources identify buildings as simply being either ‘high-’ or ‘low-rise’, others also use ‘mid-rise’ (Tamošaitienė & Gaudutis, 2013; <https://www.designingbuildings.co.uk/>). For this analysis, ‘low-’, ‘mid-’ and ‘high-rise’ are used, defined as ≤ 5 , 6–10 and ≥ 11 above-ground storeys respectively. Single-factor analysis of variance (ANOVA) tests were carried out using a 95% confidence level to determine the likelihood that mean energy use or emissions differ between groups. Where energy use or emissions were found to vary significantly with height, post-hoc Tukey honest significant difference (HSD) tests were undertaken to determine where the variation occurs.

- *Multivariate regression*

The results of the multivariate regression are then presented. GLM was carried out in R version 3.3.3 (R Development Core Team, 2008) to produce simple models of electricity and fossil fuel use and emissions for the sample. Tests were carried out to determine the most appropriate GLM distribution and link function, using the Akaike Information Criterion (AIC). A gamma distribution was found to be most suitable, reflecting the non-normal data. A log-link function, where each variable acts multiplicatively rather than additively, was also used. For further information about GLM, including an overview of the different

options, see Barber and Thompson (2004). Stepwise regression was used to identify the key variables from the available data.

It should be noted that statistical studies of this nature cannot prove the causes of any observed trends. However, where appropriate, possible explanations are discussed and further research is suggested.

Height and energy performance

The box and whisker plot diagrams summarize the performance for the overall sample. Figure 2 shows the distribution of energy use intensity (kWh/m^2) split between electricity and fossil fuels, as well as total consumption (top) and the corresponding total emissions (kgCO_2/m^2) (bottom). In each graph, the median and interquartile range can be read from the box. The whiskers represent the 10th and 90th percentiles, and the floating point is the mean. The median and first quartiles are sometimes used to define ‘typical’ and ‘good practice’ benchmarks respectively (DETR, 1998). For each variable, the overall performance is presented alongside the low/mid/high-rise split. The sample size for each result is provided on the x -axis label after the comma. The underlying data are also provided in Table 2.

The graphs in Figure 2 reveal increasing energy consumption and emissions with height. Comparing the low- and high-rise categories, mean and median electricity use increase by 76% and 85% respectively, while smaller rises are observed for fossil fuel (19% mean and 21% median). Gas represents approximately 95% of the total fossil fuel use in the sample. Consequently, its lower carbon intensity compared with mains electricity means that the emissions trend follows the electrical result: 67% and 63% increases in mean and median annual emissions respectively. In addition to increases in the typical performance, the emissions interquartile range rises by a factor of 2.3 between low- and high-rise buildings showing that it is likely to be much more difficult to achieve low-energy tall buildings compared with low-rise.

Significant differences are found with height for energy consumption (electricity, fossil fuel and total) and emissions (ANOVA, $p < 0.05$). Interestingly, however, the trends for energy use and height differ between electricity and fossil fuels. The Tukey HSD tests suggest that for electricity use the significant step is from low- to mid-rise buildings (low-to-mid and low-to-high $p < 0.05$; mid-to-high $p > 0.05$), whereas for fossil fuels the significant increase is from low- to high-rise (low-to-high and mid-to-high $p < 0.05$; low-to-mid $p > 0.05$). This difference may reflect the underlying relationships between

Figure 2. Electricity, fossil fuel and total energy use (top) and emissions (bottom) for the overall sample.

energy demand, built form and the local climate. Energy end-use breakdown information is not available for the sample. However, all else being equal, height affects fossil fuel heating demand directly through changes in air temperature and wind speed, and via mechanisms such as the stack effect. Electricity use meanwhile varies

with access to daylight and solar gains, which are affected by the height of a building relative to the surrounding buildings. A recent study of high-rise buildings found a similar result, revealing that the change in daylight availability with height depends on factors such as orientation and the neighbouring buildings (Li & Tsang, 2008).

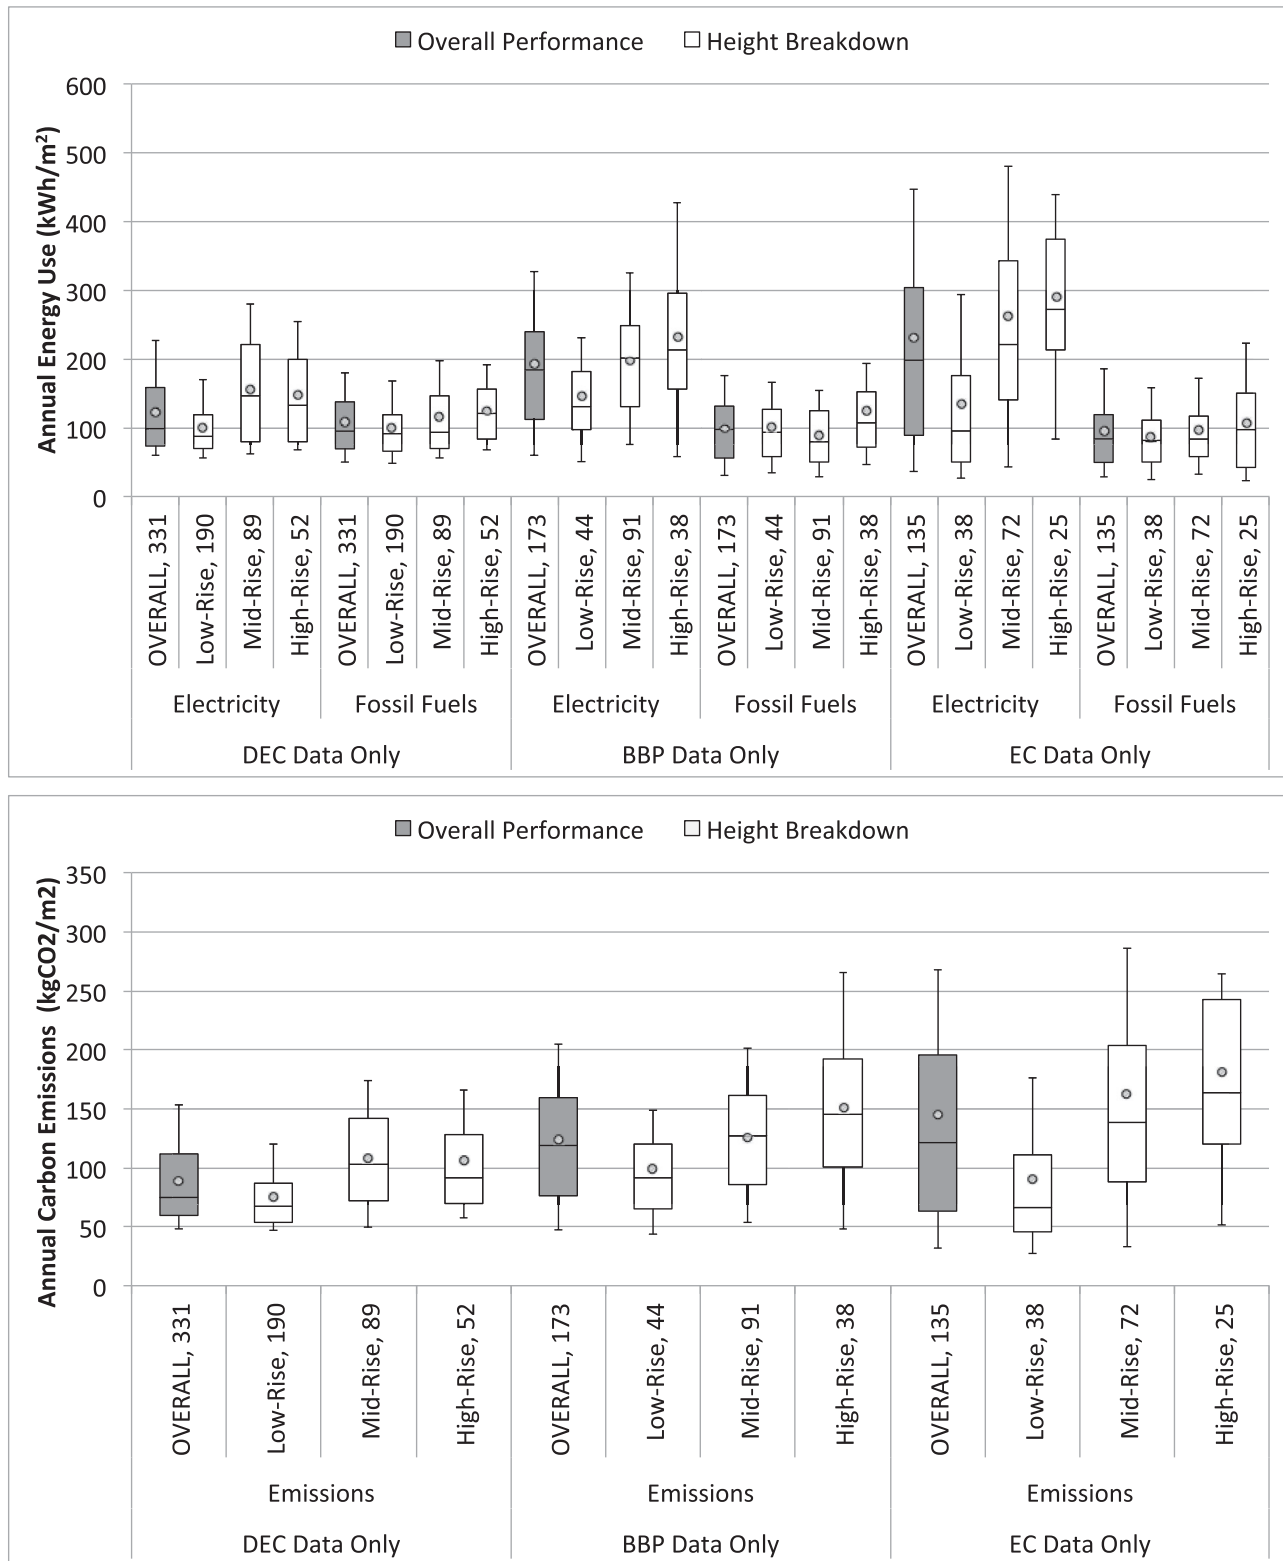

Figure 3. Electricity, fossil fuel and total energy use (top) and emissions (bottom) using energy data from each source independently.

Consequently, the observed energy–height trends will partly reflect underlying differences in the typical characteristics of low-, mid- and high-rise offices. Since the final database includes several relevant variables, multivariate

analysis was undertaken to examine the impact of these factors on the energy–height relationship.

Table 3 summarizes the characteristics of the buildings within the database, alongside the high-, mid- and

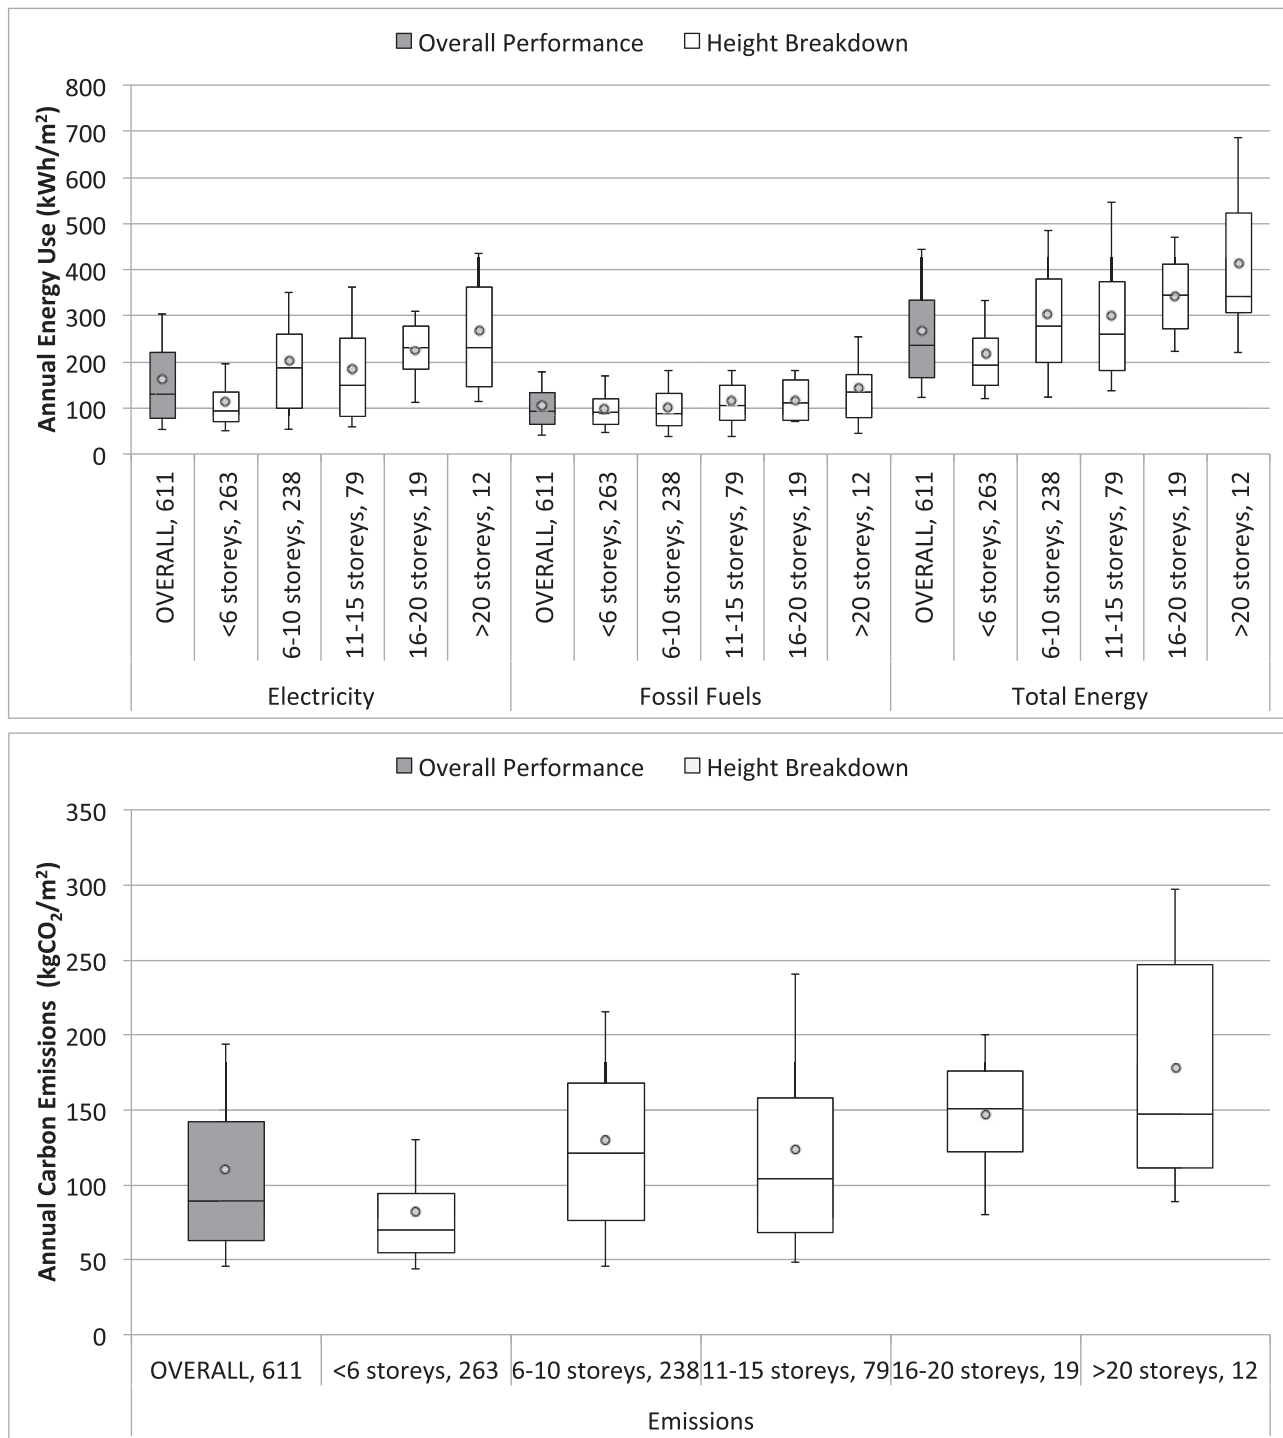

Figure 4. Electricity, fossil fuel and total energy use (top) and emissions (bottom) for the overall sample, with more detailed height breakdown.

low-rise splits. Due to the mix of sources of underlying data, complete information is not available for all of the buildings. Therefore, Table 3 details the coverage of each variable in parentheses. The energy performance breakdown associated with several of the key variables is presented for reference in Figures 5–8, along with

the variation with building height. It should be noted that while each of the variables listed is separate, they may not be truly independent choices for building designers. For example, it has been acknowledged that achieving effective natural ventilation is especially complex for high-rise buildings (Gonçalves & Bode, 2011;

Table 3. Summary of building characteristics of the low-, mid- and high-rise buildings, as well as the overall sample.

Variable	Units	Overall	Low-rise	Mid-rise	High-rise
Sample size	Number of buildings	611	263	238	110
^{A,B} Building form (external envelope area/total volume)					
Mean Ext Surface to Vol Ratio	/m	0.202 (70.7%)	0.251 (80.2%)	0.157 (72.7%)	0.149 (43.6%)
Glazing (overall envelope glazed percentage)					
Avg Glazing	Proportion	0.44 (11.8%)	0.30 (9.1%)	0.42 (8.8%)	0.59 (24.5%)

Rural village and dispersed in a sparse setting (E2)	Proportion of buildings	0.00 (100%)	0.00 (100%)	0.00 (100%)	0.00 (100%)

Note: The proportion of the sample for which each variable is known is provided in parentheses. ^A = variables included in analysis A (full coverage); ^B = variables included in analysis B (detail).

HVAC = heating, ventilation and air-conditioning.

Wood & Salib, 2013). Consequently, during the design process, the choice of HVAC may be partly influenced by building height.

The trends are generally unsurprising: compared with low-rise, taller buildings are more likely to have air-

conditioning and to be located in higher density urban areas. Also they are typically newer and have more glazing. In terms of physical form, the mean external surface area-to-volume ratio *decreases* with increasing tallness. Tall buildings, above the height of adjacent blocks,

Figure 5. Electricity, fossil fuel and total energy use (left) and emissions (right) for the sample, split by construction date.

Figure 6. Electricity, fossil fuel and total energy use (left) and emissions (right) for the sample, split by heating, ventilation and air-conditioning (HVAC) type.

Figure 7. Electricity, fossil fuel and total energy use (left) and emissions (right) for the sample, split by external surface-to-volume ratio.

might be expected to have less party wall area than short ones. However, the result means that, in general, rather than being thinner and having less party wall area, taller buildings are more compact than shorter ones. A recent study of a small sample of buildings in Hong Kong found a similar trend, with mean ratios for 1–10, 11–20 and 20 + storey buildings of 0.20, 0.16 and 0.12/m respectively (Lam et al., 2004).

Due to the large differences in coverage between the variables, the multivariate regression using stepwise selection was carried out at two scales, summarized

below. In both cases, the analysis was repeated for electricity use, fossil fuel use and emissions.

- Analysis A (full coverage): carried out using solely those variables that can currently be collected at a disaggregate level for England and Wales from the 3DStock model. The analysis included the three variables labelled with ‘A’ in Table 3, as well as ‘height’. The sample size was 432 offices.
- Analysis B (detail): carried out using more detailed building information. The five variables in Table 3

Figure 8. Electricity, fossil fuel and total energy use (left) and emissions (right) for the sample, split by average rateable value.

labelled with ‘B’ were included along with height, covering 215 offices. Glazing ratio was excluded from this analysis due to the low coverage.

Tables 4 and 5 present the results of the GLM for electricity use, fossil fuel use and emissions for analyses A and B respectively. The variables listed are those selected from the stepwise regression as optimizing the models. As previously explained, a log-link function was used. Therefore, the impact of each variable can be estimated using $\mu = \exp(x\beta)$ (Barber & Thompson, 2004). For example, for analysis A, each additional storey is associated with a 2.2% rise in electricity use and a 2.4% rise in fossil fuels (calculated from Table 4 as $\exp(0.0216) = 1.022$ and $\exp(0.0233) = 1.024$ respectively). Figure 9 shows the actual and predicted performance for electricity (top), fossil fuel (mid) and emissions (bottom) for analyses A (left) and B (right).

The results show that the available data can provide a reasonable predictor of electricity use intensity in offices. In contrast, the variables explain very little of the variation in fossil fuel consumption, even under the more detailed analysis. The coefficients of determination (r^2) for electricity and fossil fuel are 0.21 and 0.02 for the ‘full coverage’ models, but improve to 0.45 and 0.05 with the variables included in the ‘detail’ models, as shown in Figure 9. The emissions models follow electricity, reflecting the relative carbon intensities of the fuels, with r^2 -values of 0.21 and 0.45 respectively. Interestingly, the results are in stark contrast to the findings of comparable analyses carried out recently for the London residential sector (Hamilton et al., 2017). Analyzing some of the same variables, the study found no relationship of electricity consumption with height, but a strong relationship for gas, highlighting the differences in energy use between the domestic and non-domestic sectors in Britain.

Reassuringly, the overlapping variables have similar estimates between the two scales of analysis. For example, a £1/m² increase in average rateable value (ARV) is associated with a 0.1% and 0.2% rise in

electricity consumption for the ‘full coverage’ and ‘detail’ models respectively.⁴ While the observed impact appears small, the interquartile range within the sample is £180/m², corresponding to a 32% rise in electricity use from the ‘detail’ model. More detailed information about the relationship between rateable value and typical building characteristics is required to understand the drivers of the observed energy trends, but the variable may be a proxy for a qualitative building ‘prestige’ factor. This may be linked with variables such as air-conditioning, construction materials, glazing level, as well as internal use factors such as the presence of a gym or the intensity of use.

The results reveal a strong correlation between HVAC type and electricity use. Natural ventilation, for example, is associated with a 41% reduction in electricity use compared with air-conditioning, while mechanical ventilation is between these extremes (26% reduction). It is interesting to note that, despite a difference in fossil fuel use shown in Figure 6 (6.3% reduction in mean consumption between air-conditioned and naturally ventilated buildings), HVAC type was excluded during the stepwise process from the final fossil fuel consumption model. This suggests that the net impact of HVAC type is predominantly on cooling and ventilation, rather than on heating. A similar trend can be found in DETR (1998). The benchmarks suggest a 166% rise in typical electricity use between naturally ventilated ‘type 2’ and air-conditioned ‘type 3’ offices (with 40% attributable to cooling, fans and pumps), compared with only an 18% increase in typical fossil fuel use.⁵

The models suggest no clear relationship between energy consumption and location (urban/rural) as measured by the particular metric used (rural urban classification – RUC). This classification is included in the ‘full coverage’ electricity and emissions models. However, the estimates show no simple trend, and the variable is excluded from the ‘detail’ models. It is worth noting, however, that RUC is a fairly crude descriptor

of urban character and location, and that the postcode area (at which RUC is measured) varies significantly. Consequently, it may not provide a useful indication of the surroundings of each building, for energy performance purposes. Alternative aggregate geographic data are available for the UK, including land use and population data. However, these are still broad proxies for urban form, and provided at varying levels of aggregation. It may be better to explore the relationship between urban form and energy use further using more detailed quantitative metrics. 3DStock provides a detailed

description of built form at a disaggregate scale. Therefore, work is currently ongoing to integrate calculations that describe the physical surroundings for each building in detail.

Regulations covering the conservation of fuel and power were introduced for new non-domestic buildings in the UK in 1974 and have grown progressively more stringent over time, setting minimum requirements for building envelope and plant characteristics, as well as standardized methods for estimating energy consumption (King, 2007). Furthermore, while modern buildings

may have better insulation and infiltration standards than older ones at the point of construction, fabric and plant efficiency may also deteriorate over time. Therefore, it is interesting that no correlation was found between construction date and fossil fuel use.

The results suggest that newer buildings are associated with higher electricity use. A possible explanation for this electricity trend may be that modern buildings are used more intensively than older ones, through higher occupancy density and information technology (IT) use. It should be noted, however, that more intensive use typically results in higher internal gains, which may be expected to offset some of the demand for space heating; but this is not reflected in the fossil fuel use. Overall, the model suggests that between offices constructed in 1974 and 2010, there is an 18.4% increase in electricity use intensity. The fact that the buildings designed to meet the toughest regulations have the highest emissions highlights the difficulty in improving the building stock as a whole.

The external surface-to-volume ratio provides a description of a building's overall compactness, accounting for party boundaries and building size. Theoretically, the variable is related to the potential for heat transfer, solar gains, daylight, natural ventilation and infiltration, which all occur at the external envelope. In this light, it is interesting to note that neither model finds a significant relationship with fossil fuel use. A possible explanation for the lack of any clear trend may be glazing ratio, which drops from a mean of 60% to 21% from the most to least compact buildings. Within the database, only 45 buildings include data on both glazing and external surface-to-volume ratio, therefore this subsample is tiny. However, similar positive relationships between average glazing and compactness have been observed in two studies of high-rise buildings in Hong Kong (Lam et al., 2004; Li & Tsang, 2008), as well as the US (Winiarski, Halverson, & Jiang, 2008). In the former, for example, the mean glazing ratios for the most and least compact quartile of buildings were 47% and 30% respectively. If it is true that building compactness correlates negatively with glazing, then the corresponding effect on building *U*-values may explain the trend. Significantly, Steemers (2003) suggests that in order to minimize energy consumption, glazing ratios should decrease with height, while Raji, Tenpierik, and van den Dobbelsteen (2016) suggest that window-to-wall glazing ratios should be between 30% and 50% depending on the thermal performance of the envelope. External surface-to-volume ratio is found in the present work to be associated with a drop in electricity use: from the 'detail' model, an increase of 0.1/m corresponds to an 18% drop in electricity consumption. This suggests that the increased access to daylight and opportunity for

natural ventilation may offset the corresponding added exposure to solar gains.

Across both scales of analysis, the results show that height is a significant predictor of energy use, even accounting for other variables. This means that the energy/height trends observed in Figure 2 are not simply a reflection of the fact that low-, mid- and high-rise buildings have different characteristics (Table 3). From the 'detail' model, one additional storey is associated with a 2.4% increase in electricity use and a 2.9% increase in fossil fuel use. The corresponding impact on carbon emissions is a rise of 2.5%. Based on the mean performance of the sample, this indicates that changing from low- to high-rise (from five to 15 storeys) results in increases in mean electricity and fossil fuel consumption of 44 and 33 kWh/m² respectively.

Building height influences energy consumption directly through mechanisms such as changes in external temperature and wind speed with altitude, access to daylight and solar gains, as well as the need for lifts (elevators). However, the net impact on any specific building will depend on factors such as occupancy behaviour, building design and the internal systems. For example, reductions in artificial lighting will only be achieved if the controls are connected to daylight sensors. However, this may not be the case: a survey of an office in the US found poor daylight controls in reality due to issues such as interior layouts (Day, Theodorson, & Van Den Wymelenberg, 2012), while a survey of 15 offices in the UK found very poor integration between the solar and daylighting controls (Cunill, Serra, & Wilson, 2007). Examination of energy end-uses in conjunction with building modelling will be required to determine the underlying drivers for the observed trends. However, the fact that height correlates positively with both electricity and fossil fuel use suggests that any reduction in artificial lighting demand in taller buildings due to greater access to daylight is overwhelmed by other factors, such as the need to deal with increased solar gains.

Conclusions and further work

This paper presents the results of an examination of the performance of a sample of 611 offices in England and Wales. Disaggregate energy data from the DEC, BBP and EC databases were used in conjunction with other building data as well as the results of a survey undertaken by the authors. Statistical tests were carried out to explore the drivers of energy consumption, with a focus on understanding the impact of building height.

Considering the overall change in performance with height, it was found that mean electricity and fossil fuel use increase by 77% and 20% respectively between low-

and high-rise offices (defined as ≤ 5 and > 10 storeys respectively), with a corresponding rise in mean CO₂ emissions of 67%. The variation in 10th percentile emissions with height is small, suggesting that achieving low-carbon performance in tall buildings is possible. However, a near doubling of 75th percentile emissions indicates that this is rarely achieved. Within the sample, the low-, mid- and high-rise offices have different typical characteristics. Therefore, GLM was used to examine the underlying drivers of the observed energy–height trends. Height is shown to be a significant predictor of energy, even accounting for variables such as HVAC type and date of construction. Each storey is associated with 2.4% and 2.9% increases in mean electricity and fossil fuel use respectively, corresponding to a 31% increase in emissions between low- and high-rise buildings.

The direct effects of height on energy consumption are a result of the interaction between a building and its local environment. For example, all other things being equal, an increase in height will raise the amount of daylight and solar gains entering a building, potentially reducing the demand for artificial light in its perimeter zones, but increasing the risk of overheating. Data on the energy end-use breakdown are not available for this study. However, the results suggest that the benefits associated with height, such as a reduced need for artificial lighting, may be outstripped by factors that increase electricity and fossil fuel use, such as an increased demand for cooling or mechanical ventilation associated with solar gains.

This paper is part of an ongoing study examining the relationship between energy consumption and height within the UK building stock. The study will continue, focusing on two areas of interest:

- *Thermal modelling*

Statistical studies of the kind presented here cannot determine causality. Work is currently ongoing to use building modelling to examine the mechanisms that drive the observed trends. In particular, this will help to quantify the theoretical relative impact of height, envelope and surrounding buildings on the demand for electricity and fossil fuel.

- *Character of the urban area*

Solar gains and daylight will vary with the relative height of a building compared with its surroundings, rather than its absolute height. However, the existing publicly available urban form data were found to be insufficiently detailed for use as an indicator of building energy use. Therefore, work is ongoing to integrate detailed and quantitative descriptors of urban form into 3DStock to better describe the relationship between each building and its local area.

The analysis presented in this paper shows that increases in building height are associated with higher electricity and fossil fuel consumption in offices. The drivers for the observed trends are not clear cut. However, the available data suggest that they cannot simply be explained by factors such as the presence of air-conditioning. It has previously been suggested that it is ‘undoubtedly true’ that tall buildings were, by their nature, more energy intensive than shorter ones (Cangelli & Fais, 2012, p. 40). While low-emission, high-rise buildings exist within the sample, the analysis suggests that they are still the exceptions to the rule.

Notes

1. The character of vertical transportation is also linked to building height. However, a study of energy end-use in high-rise offices in Hong Kong found that this accounts for only 3.2% of total energy use (Lam et al., 2004), in line with similar figures for the UK (DETR, 1998).
2. This result is not actually reported but can be inferred from data included in the paper.
3. The total sample sizes appear to be larger than the previous graph because some buildings appear in multiple data sets.
4. Rateable value is calculated by the UK government for the purposes of assessing property taxes or ‘rates’.
5. The office types defined by DETR (1998) include a package of characteristics, not just HVAC type, so the comparison should be treated with caution. However, data are provided on the energy end-use breakdown.
