**Introduction**

This new diagnostic consensus guideline is a joint project of the European Crohn’s and Colitis Organisation [ECCO] and the European Society of Gastrointestinal and Abdominal Radiology [ESGAR] that now merges the former ECCO-ESGAR Imaging Guideline and the former ECCO Endoscopy Guideline, also including laboratory parameters. It has been drafted by 30 ECCO and ESGAR members from 17 European countries. All the authors recognize the work of and are grateful to previous ECCO and ESGAR members who contributed to creating the earlier consensus guidelines on imaging and endoscopy.

The former guidelines have been condensed into this new diagnostic consensus guideline which consists of two papers: the first detailing assessment at initial diagnosis, to monitor treatment and for the detection of complications; the second dealing with the available scoring systems and general considerations regarding the different diagnostic tools.

The strategy to define consensus was similar to that previously described in other ECCO consensus guidelines [available at www.ecco-ibd.eu]. Briefly, an open call for participants was made, with ECCO participants selected by the Guidelines’ Committee of ECCO [known as GuiCom] on the basis of their publication record and a personal statement and ESGAR participants nominated by ESGAR. The following working parties were established: diagnostics at initial diagnosis, diagnostics for monitoring treatment in patients with known IBD, diagnostics for the detection of complications, scores for IBD, and general principles and technical aspects.

Provisional guideline statements and supporting text were written following a comprehensive literature review, then refined following two voting rounds. The first voting round introduced a more comprehensive voting procedure, in which each Guidelines participants voted on all statements by explicitly reviewing those statements together with their respective supporting text and references. The second voting round included optional national representative participation of ECCO’s 36 member countries and ESGAR’s 28 member countries. The level of evidence was graded according to the Oxford Centre for Evidence-Based Medicine [www.cebm.net]. The ECCO statements were finalized by the authors at a face-to-face meeting in Barcelona in October 2017 and represent consensus with agreement of at least 80% of the present participants. Consensus statements are
intended to be read in context with their qualifying comments and not in isolation. The supporting text was then finalised under the direction of each working group leader [SV, TK, GF, VA, EC], before being integrated by the consensus leaders [CM, JS, AS].

Chapter 1: Initial Diagnosis

**Statement 1.1. ECCO-ESGAR Diagnostics GL (2018)**

A single reference standard for the diagnosis of Crohn’s disease (CD) or ulcerative colitis (UC) does not exist. The diagnosis of CD or UC is based on a combination of clinical, biochemical, stool, endoscopic, cross-sectional imaging, and histological investigations [EL5]

A single reference standard for the diagnosis of Crohn’s disease (CD) or ulcerative colitis (UC) does not exist. At a minimum, the diagnosis of CD or UC is based on a combination of clinical, biochemical, stool, endoscopic, and histological investigations. When CD is suspected, it may be necessary to visualise (radiologically) the small intestine. Infectious colitis, including *Clostridium difficile*, should be excluded.

**Statement 1.2. ECCO-ESGAR Diagnostics GL (2018)**

Genetic or serological testing is currently not recommended for routine diagnosis of CD or UC [EL3]

**Statement 1.3. ECCO-ESGAR Diagnostics GL (2018)**

On diagnosis, complimentary investigations should focus on markers of disease activity [EL2], malnutrition, or malabsorption [EL5]. Immunization status should be assessed. Consider screening for latent tuberculosis [EL5]

At diagnosis, every patient should have a biochemical assessment with full blood count, inflammatory markers (C-reactive protein [CRP]), electrolytes, liver enzymes, and a stool sample for microbiological analysis, including *C difficile*. [1, 2]. The full blood count may reveal thrombocytosis (due to an inflammatory response), anaemia, and leucocytosis. The presence of raised inflammatory markers (CRP) broadly correlates with clinical severity in CD [1] but less so in UC except in the case of acute severe colitis [2]. However, laboratory markers of chronic inflammation may be normal in both UC and CD [3, 4]. As raised CRP, leucocytosis, or both are not IBD-specific, their presence cannot differentiate IBD from infectious (or other causes of) colitis. Apart from biochemical evidence of malnutrition, hypoalbuminaemia can reflect severe inflammation; however this is not superior to CRP [4].
Faecal calprotectin (FC), a neutrophil-derived protein, appears to be the most sensitive marker of intestinal inflammation in IBD. Other neutrophil-derived proteins are elastase, lysozyme, and lactoferrin [3, 5-10]. Calprotectin values correlate well with endoscopic indices of disease activity and are thus important in various clinical settings, including initial diagnosis, diagnosis of relapse, and response to treatment [11-15].

In the initial investigations of a patient with gastrointestinal symptoms and a raised stool marker of inflammation, an ileocolonoscopy should be performed. An exact cut-off value that distinguishes between IBD and functional bowel diseases does not exist [16, 17]. However, good diagnostic accuracy can potentially be obtained at a cut-off value of 150 µg/g, as recently suggested in a meta-analysis [18]. However, FC lacks the specificity to discriminate between IBD and other causes of intestinal inflammation [7].

During the diagnostic process of IBD, gastrointestinal infections should always be excluded [1, 2]. Loose stools for more than 6 weeks usually discriminate IBD-associated colitis from most cases of infectious diarrhoea [19]. Stool specimens should be obtained to exclude common pathogens and specifically assayed for C difficile toxin. Additional tests may be tailored according to medical history, such as those who have travelled abroad. This may include the assessment for ova, cysts, and parasites [20].

Serologic markers may be used to support a diagnosis, though the accuracy of the best available tests (pANCA and ASCAs) is rather limited and hence ineffective at differentiating colonic CD from UC [21, 22]. Similarly, the additional diagnostic value of anti-glycan and antimicrobial antibodies such as anti-OmpC and CBir1 is small [3, 4, 23, 24]. Likewise, although more than 250 IBD-associated susceptibility SNPs have been identified, genetic testing for common variants does not allow diagnosis of IBD [25].

Some infections are preventable and the risk for severe infections during immunosuppression can be decreased or eliminated if the patient is adequately vaccinated. Vaccination is best given before initiating immunomodulatory therapy. The following should be assessed as necessary before vaccination: hepatitis B surface antibody, hepatitis B antigen, hepatitis B core antibody, hepatitis A IgG, measles serology, and varicella serology. Additional baseline tests recommended at diagnosis include hepatitis C serology, Epstein-Barr serology and human immunodeficiency virus serology, after appropriate counselling [26].

Statement 1.4. ECCO-ESGAR Diagnostics GL (2018)

(ECCO Anaemia Guideline: statement 1D in Dignass et al.)
Diagnostic criteria for iron deficiency depend on the level of inflammation. In patients without clinical, endoscopic, or biochemical evidence of active disease, serum ferritin <30 µg/L is an appropriate criterion [EL2]. In the presence of inflammation, serum ferritin up to 100 µg/L may still be consistent with iron deficiency [EL4].

Statement 1.5. ECCO-ESGAR Diagnostics GL (2018)

(ECCO Anaemia Guideline: statement 1E in Dignass et al.)

In the presence of biochemical or clinical evidence of inflammation, the diagnostic criteria for anaemia of chronic disease are serum ferritin >100 µg/L and transferrin saturation <20%. If the serum ferritin level is between 30 and 100 µg/L, a combination of true iron deficiency and anaemia of chronic disease is likely [EL2].

One of the most frequent complications of IBD is anaemia (haemoglobin [Hb] <13 g/dL for men and <12 g/dL for women), which may affect patients’ quality of life and should hence be evaluated at initial diagnosis [27-29]. In cases of documented anaemia, further workup should start from the evaluation of mean corpuscular volume (MCV). Microcytic anaemia is usually the most common type of anaemia in IBD, which usually indicates iron-deficiency anaemia [30]. Macrocytosis may indicate vitamin B12 or folate deficiency and is also commonly seen during thiopurine therapy, whereas normocytosis may suggest anaemia of chronic disease (ACD) [31]. The distinction between iron deficiency anaemia and ACD or a mixed picture of micro-/and macrocytosis is important as treatment is different between these conditions.

The diagnosis of iron deficiency depends on the level of inflammation. In patients without clinical, endoscopic, or biochemical evidence of active disease, the diagnosis is made when serum ferritin is <30 µg/L [32, 33]. In the presence of inflammation, serum ferritin up to 100 µg/L may still be compatible with iron deficiency [34, 35]. Other markers suggestive of iron deficiency anaemia are low MCV, raised red cell distribution width (RDW), microcytic hypochromic pencil red cells on blood film, low serum iron, raised total iron-binding capacity, and transferrin saturation of <16% [36].

For suspected IBD, ileocolonoscopy with biopsies from inflamed and uninflamed segments are required to establish diagnosis [EL1], except in the case of acute severe colitis in which sigmoidoscopy may be sufficient [EL3].

Statement 1.7. ECCO-ESGAR Diagnostics GL (2018)
No endoscopic feature is specific for CD or UC. The most useful endoscopic features of UC are considered to be continuous and confluent colonic involvement with clear demarcation of inflammation and rectal involvement [EL2]. The most useful endoscopic features in CD are discontinuous lesions, presence of strictures and fistulas, and perianal involvement [EL2].

For a reliable diagnosis of UC and CD, ileocolonoscopy with a minimum of two biopsies from the inflamed regions should be obtained [37-40]. Additional biopsies from uninflamed regions and every colonic segment (including the rectum, especially in UC) may be helpful in the diagnostic process and to diagnose microscopic pathology. The distinction of infectious colitis from IBD is usually characterised by preserved crypt architecture and acute inflammation [41], however in very early disease the architecture can be preserved. Other differential diagnoses include segmental colitis associated with diverticulitis (SCAD) and ischaemic colitis [42-45].

Granulomas and focal crypt architectural abnormalities, in conjunction with focal or patchy chronic inflammation (defined by the presence of lymphocytes and plasma cells), or mucin preservation at active sites are CD-related histological features. The patchy nature of the inflammation is only diagnostic in untreated adult patients [46-50]. One single feature is not considered to be diagnostic, though there are no data available as to how many features must be present in an endoscopically derived biopsy before a firm diagnosis can be made [40]. On surgical samples, a diagnosis of CD should be made when at least three histological features suggestive of CD (segmental crypt architectural abnormalities and mucin depletion, mucin preservation at the active sites, and focal chronic inflammation without crypt atrophy) are present in the absence of granulomas, or when an epithelioid granuloma is present with one other feature [39, 40].

Focal or diffuse basal plasmacytosis has been recognized as the earliest feature with the highest predictive value for UC diagnosis. This can be identified in 38% of patients within 2 weeks after symptom presentation. During this period, the distribution pattern of basal plasmacytosis is focal but may eventually change into a diffuse pattern throughout the disease course. Only about 20% of patients show crypt distortion within 2 weeks of the first symptoms of colitis. The distinction from infectious colitis is therefore a major concern. Widespread mucosal or crypt architectural distortion, mucosal atrophy, and an irregular or villous mucosal surface appear later, at least 4 weeks after presentation [41, 51]. Not all microscopic features found in UC are observed in early disease. A correct diagnosis of UC is reached in approximately 75% of cases where two or three features are present. However, the exact number of features needed for UC diagnosis has not been established [37].

Due to the increased risk of bowel perforation, complete ileocolonoscopy is not usually recommended in case of acute severe colitis [52]. However, a study by Terheggen et al. demonstrated that there was no relationship between complication rate and disease activity [53].
Flexible sigmoidoscopy can be safely performed to establish the diagnosis of UC. Phosphate enema preparation before flexible sigmoidoscopy has been reported to be safe in this setting [54], though it is generally advised to avoid purgatives, especially fleet enemas and oral sodium phosphate preparations [55].

**Statement 1.8. ECCO-ESGAR Diagnostics GL (2018)**

Patients with clinical suspicion of CD and with normal endoscopy should be considered for small-bowel capsule endoscopy (SBCE) evaluation or cross-sectional imaging [EL2]. If stenotic disease is suspected, risk of retention should be assessed [EL2].

Small-bowel capsule endoscopy (SBCE) is a sensitive tool to detect mucosal abnormalities in the small bowel. There are currently two validated indexes available, namely the Capsule Endoscopy Crohn’s Disease Activity Index (CECDAI) and the Lewis score, which assess the disease location and activity of small bowel involvement. Both will be discussed further in this guideline. The diagnostic yield of SBCE is comparable to other modalities (MR enterography, small intestine contrast ultrasound [SICUS]), apart from proximal small bowel involvement for which SBCE seems superior [56]. As proximal small bowel involvement is associated with a higher risk of surgery [57], this superior accuracy might have prognostic value [56]. Data from small, prospective cohorts suggest that the diagnostic yield of SBCE is highest in patients with suggestive CD symptoms and increased inflammatory markers [58, 59], although this was not replicated in larger retrospective cohorts [60, 61]. However, the likelihood of positive diagnosis is very low in patients with suspected CD with FC <50 μg/g [62]. Additionally, all patients with unclassified IBD at diagnosis could also be considered for SBCE.

Similarly, as normal imaging tests such as IUS and MR enterography of the small bowel cannot entirely exclude small-bowel involvement, CD patients with normal radiological tests can be considered for additional SBCE, e.g. in patients with clinical signs suspicious of small bowel Crohn’s disease and elevated Calprotectin and/or otherwise unexplained iron deficiency anaemia. Contraindications for SBCE include gastrointestinal obstruction, strictures, and swallowing disorders [63-65]. The risk of capsule retention in patients with suspected CD without obstructive symptoms and without history of small bowel resection or known stenosis is low and comparable to that of obscure GI bleeding [66-69]. Data on retention rates in patients with CD varies from 2 to 13% in patients with established CD to approximately 1.5% in patients with suspected CD [70]. If small-bowel stenosis is not firmly excluded, a patency capsule can be used to confirm small bowel patency before performing SBCE. All patency capsules are dissolved within 72 hours. SBCE is considered safe if the patency capsule is excreted before 30 hours, an intact capsule is excreted after 30 hours, or passage to the colon of an intact patency capsule has been radiologically confirmed [71]. Yadav et al. demonstrated that the negative predictive value (NPV) for patency capsules and radiological tests...
were not significantly different [72]. Thus, if either test is negative before SBCE, the patient will most likely pass the capsule without incident. Radiological tests have the advantage of eliminating false positive results, as they do not depend on intestinal motility. However, cross-sectional imaging is significantly less accurate in the evaluation of functional small-bowel patency, frequently overestimating the risk of obstruction. In a recent study evaluating the accuracy of MRI for prediction of patency capsule retention in patients with established small-bowel CD, the sensitivity and specificity of MR enterography were 92.3% and 59%, respectively. Thus, if the decision to administer SBCE was based on imaging and not patency capsule results, at least 40% of the patients would not have undergone SBCE [57]. Questions about optimal bowel preparation, selection of patients, and the optimal reading protocol remain to be clarified [73] and are discussed in more detail later in this guideline.

Statement 1.9. ECCO-ESGAR Diagnostics GL (2018)

Upper GI endoscopy is recommended in patients with CD with upper GI symptoms but not for asymptomatic newly diagnosed adult IBD patients [ELS]

CD involving the upper GI tract (oesophagus, stomach, and duodenum) is almost invariably accompanied by small or large bowel involvement [74-76]. Patients who have upper gastrointestinal symptoms such as nausea, dyspepsia, and vomiting will benefit from upper GI endoscopy [77]. Whether asymptomatic adult CD patients should routinely undergo oesophago-gastroduodenoscopy is still debated. However, a prospective registry reported a higher prevalence of upper GI involvement in asymptomatic CD patients than initially expected [77], suggesting a place for a standard gastroscopy at CD diagnosis to correctly evaluate disease extent. When it is difficult to obtain a histological diagnosis of CD, upper GI endoscopy may support the diagnosis, as focal gastritis may be a feature of CD [74].

Finally, upper GI endoscopy is mandatory in patients with suspected concomitant coeliac disease [78].

The sensitivity and specificity of radiological imaging techniques in the assessment of upper GI CD is unclear, with publications limited to case reports and small series. Radiological assessment of patients should be reserved only for those patients with CD and upper GI symptoms in whom endoscopic assessment has failed or is incomplete. Radiological assessment of the upper GI tract should not form part of routine diagnostic workup.

Statement 1.10. ECCO-ESGAR Diagnostics GL (2018)
All newly diagnosed CD patients should undergo small-bowel assessment (intestinal ultrasound, MR enterography and/or capsule endoscopy) [EL2]

The ileocaecal region is usually visualized adequately endoscopically. The proximal ileum and jejunum can be more difficult to assess. A study by Samuel et al. evaluated CD patients with CT enterography and ileocolonoscopy. From the group of patients with normal results from ileoscopy, 53.7% of these patients had active, small-bowel CD. Ileoscopic examination can thus miss CD of the terminal ileum, as the disease can skip the distal ileum or is confined to the intramural portion of the bowel wall and mesentery [79].

CT and MRI are both used as to assess the small intestine. Both techniques can establish disease extent and activity based on wall thickness and increased intravenous contrast enhancement [80]. A direct comparison of CT and MRI for the diagnosis of a variety of small intestinal lesions demonstrates high sensitivity and specificity, similar for both techniques [81-83]. Due to the absence of radiation, MRI should be preferred over CT particularly in young patients [81].

A study by Messaris et al. demonstrated that routine use of MR enterography can alter the management of patients with ileal or ileocolonic CD. In this study, 64 (53%) of patients had additional medical management for active inflammation and 16% underwent an operation for complicated CD or medical intractability. The intraoperative findings were consistent with the MRI diagnosis in all surgically treated patients [84]. Similarly, Mendoza et al. demonstrated that MRI influenced a change in treatment (medical or surgical) in 83 (55.3%) patients. The change in management even affected those patients who were already diagnosed with ileal or ileocolonic CD [85].

A direct comparison of intestinal ultrasound (IUS) and MRI performed in 234 consecutive suspected CD patients showed a similar diagnostic accuracy in detecting small-bowel CD. Sensitivity, specificity, positive predictive value (PPV), and NPV for CD diagnosis were 94%, 97%, 97%, and 94% for IUS and 96%, 94%, 94%, and 96% for MR enterography, respectively. IUS was less accurate than MR enterography in defining CD extent (r=0.69), whereas the concordance in terms of CD location between the two procedures was high (κ=0.81). MR enterography also showed a fair concordance with IUS regarding strictures (κ=0.82) and abscesses (κ=0.88), with better detection of enterointestinal fistulas (κ=0.67) [86].

A UK multi-centre trial of 284 newly diagnosed or suspected relapse Crohn’s disease patients showed that MRE had significantly greater sensitivity for small bowel disease extent (presence and location) compared to US (80% vs.70% respectively). MRE also had significantly greater specificity than US (95 vs 81% respectively). For detecting the presence of small bowel disease irrespective of
location, US sensitivity was 92%, compared to 97% for MRE. Sensitivity for active SB disease was significantly greater for MRE than US (96% vs. 90% [82 to 95]) [87].

A review by Calabrese et al. reported that IUS had a 79.7% sensitivity and 96.7% specificity for the diagnosis of suspected CD and an 89% sensitivity and 94.3% specificity in assessment of patients with known CD with lower accuracy for detecting proximal small-bowel lesions. Administration of an oral contrast agent improved the sensitivity and specificity in determining CD lesions [88].

In a systematic review, the diagnostic yield of SBCE is comparable to MR enterography and IUS, apart from proximal small-bowel involvement for which SBCE seems to be superior. The odds ratio (OR) for diagnosis via SBCE versus MR enterography was 0.56 (95% confidence interval [CI] 0.28–1.13; P=0.1) and the OR for SBCE had superior diagnostic yield for proximal small-bowel disease with an OR of 2.62 (95% CI 1.10–6.53; P=0.03) [56].

A range of factors, including local availability and expertise, determines the choice of small-bowel imaging modality. For initial assessment and exclusion of CD, SBCE, IUS, MR enterography, and CT enterography are superior to small-bowel follow through (SBFT) [83, 89]. Cross-sectional imaging of the small bowel should be performed in preference to SBCE where clinical symptoms indicate obstructive or stricturing small-bowel CD.

Statement 1.11. ECCO-ESGAR Diagnostics GL (2018)

The presence of at least three small-intestine ulcers in SBCE highly suggests a diagnosis of CD, provided the patient has not been using NSAIDS for at least one month before the test [EL4]

In patients with negative endoscopy and suspicion of CD on MRI or small-bowel capsule endoscopy, device-assisted enteroscopy may be performed if diagnosis needs to be confirmed endoscopically and histologically [EL3]

Several small studies have evaluated the utility of SBCE for reclassification of patients with UC and with unclassified IBD and reported varying reclassification rates. Although a normal SBCE cannot exclude CD, the presence of small-bowel pathology that is consistent with CD enables reclassification [90-95]. In a study by Mow et al., multiple ulcerations (≥3 ulcerations) were considered diagnostic for CD and were observed in 26% of cases [90]. Similar data have been reported by Monteiro et al.; 25% of patients with unclassified IBD were found to have small-bowel involvement consistent with CD. Still, 37% of patients remained IBD unclassified during further follow up [95].
Perianal manifestations result in fistula and abscess formation in 21 to 54% of CD patients [96-99] and more frequently (up to 41%) in patients with isolated colonic involvement compared with isolated ileal disease (12%) [97]. A thorough baseline clinical examination of the perianal area should to be performed in all newly diagnosed patients at ileocolonoscopy, as symptoms can be initially very mild.

Diagnosis and classification of perianal disease is usually achieved via a combination of both clinical and imaging findings [100]. Fistulas can be considered ‘simple’ if they are low (of superficial or low intersphincteric or low transsphincteric origin), have a single external opening, and lack evidence of abscesses, rectovaginal fistulas, or anorectal strictures. ‘Complex’ fistulas are high (of high intersphincteric or high transsphincteric or extrasphincteric or suprasphincteric origin), may have multiple external openings, and can be associated with the presence of abscesses, rectovaginal fistulas, or anorectal strictures [101].

A perianal abscess may be the first presentation of CD in a healthy individual [102]. Patients with an unexplained fistula and suspicion of CD should therefore undergo ileocolonoscopy to assess mucosal inflammation in the ileum or colon that may indicate CD [103]. In case of a negative conventional workup including ileocolonoscopy, capsule endoscopy can provide an incremental diagnostic yield of 24% [104].

Proctosigmoidoscopy or ileocolonoscopy (if the proximal colon also needs evaluation) should be performed routinely in all patients with perianal CD to assess disease extent, severity of luminal inflammation, presence of internal openings, and to exclude complications such as strictures and cancer [103, 105]. Proctitis is a known risk factor of persistent non-healing fistula tracts and increased proctectomy rates [106] and often indicates complex fistulae and associated complications such as abscesses [100]. Undiagnosed extensions and abscesses are major causes of recurrent disease after attempted surgical cure [100].
Chapter 2: Monitoring known IBD

2.1. Monitoring therapeutic success

Statement 2.1.1.1. ECCO-ESGAR Diagnostics GL (2018)
Response to treatment in active ulcerative colitis (UC) should be determined by a combination of clinical parameters, endoscopy, and laboratory markers such as C-reactive protein (CRP) and faecal calprotectin [EL1]

Statement 2.1.1.2. ECCO-ESGAR Diagnostics GL (2018)
In patients with UC who clinically respond to medical therapy, mucosal healing (MH) should be determined endoscopically or by faecal calprotectin (FC) approximately 3 to 6 months after treatment initiation [EL5]

Statement 2.1.1.3. ECCO-ESGAR Diagnostics GL (2018)
Endoscopic reassessment in UC should be considered in case of severe relapse, persistent disease activity, new unexplained symptoms, and prior to switch of therapy [EL5]. Sigmoidoscopy might be sufficient in most patients [EL5]

There is no gold standard in determination of therapeutic success in ulcerative colitis (UC). For follow up of active disease in UC, endoscopy remains the reference standard. As UC involves the mucosa continuously from the rectum, colonoscopy with biopsies is still the reference standard for assessment of disease extent. However, flexible sigmoidoscopy is adequate for assessment of disease activity in most patients.

Several studies determined the benefit of mucosal healing (MH) in patients with UC. In a prospective Norwegian cohort, MH was associated with reduced risk of colectomy in UC and lower inflammation at 5 years [107]. These findings could be confirmed by a recent meta-analysis [108]. In this meta-analysis patients with MH had pooled odds ratio of 4.50 for achieving long-term (after at least 52 weeks) clinical remission (95% confidence interval [CI], 2.12-9.52), 4.15 for remaining free of colectomy (95% CI, 2.53-6.81), 8.40 for achieving long-term MH (95% CI, 3.13-22.53), and 9.70 for achieving long-term corticosteroid-free clinical remission (95% CI, 0.94-99.67), compared with patients without MH. In accordance with these findings, an international consensus panel recently recommended MH as an important therapeutic goal for UC [109].
There is no evidence-based consensus of when best to reassess disease activity after a change in therapy. However, in most induction studies MH has been determined approximately 2 to 3 months after starting treatment [110]. Although this appears to be an appropriate time point to reassess, the exact timing will depend upon clinical necessity and the chosen therapy.

There is a growing need to replace invasive diagnostics by surrogate noninvasive markers. Blood parameters are convenient. However, C-reactive protein (CRP) has low sensitivity in determining active mucosal disease in UC, with serum levels frequently within normal limits even in active disease [111]. The exception is in patients with elevated CRP levels during disease flare, for whom CRP might be used as a suitable follow up. A more accurate surrogate marker of MH is faecal calprotectin (FC). There is a strong correlation between endoscopic inflammation and FC in UC. In a study with 52 patients, FC correlated with clinical Mayo score ($r=0.63; P<0.0001$) [112]. This correlation was strengthened by adding the endoscopic subscore ($r=0.90; P<0.0001$). The endoscopic subscore also correlated independently with FC ($r=0.96; P<0.0001$). The use of FC as a surrogate marker for MH in UC has also been demonstrated in several other studies [113, 114].

Another potential noninvasive alternative for monitoring active UC is intestinal ultrasound (IUS). In four studies that assessed the diagnostic accuracy of IUS in a total of 74 patients, sensitivities ranged from 48 to 100% and specificities ranged from 82 to 90%. Current evidence indicates that the diagnostic accuracy of IUS in UC is also related to disease site, as sensitivity is high for sigmoid or descending colonic disease (reaching 97%) [115] but low for rectal disease [116]. The utility of IUS for assessing activity has been assessed in a study including 38 IBD patients (12 UC) and 6 controls [117]. The mean colonic wall thickness was 3.2 mm in both Crohn’s disease (CD) and UC, being higher in moderately (n=46; $P<0.001$) or severely inflamed bowels (n=20; $P<0.001$) compared with normal segments (n=58). There are only few studies that address the use of IUS for follow up of patients with active UC under treatment. In a recent study of 83 patients with moderate-to-severe UC, endoscopic and IUS severity was graded 0 to 3 at entry according to validated scores [116]. Of the recruited patients, 74 patients who were clinically responsive to steroids were followed up with repeated colonoscopy and IUS at 3, 9, and 15 months from recruitment. A high and consistent concordance was demonstrated between endoscopic and IUS scores (weighted $\kappa$ between 0.76 and 0.90). Thus, IUS may be a potential alternative to endoscopy to assess response to treatment of severe UC.

As IUS has significant limitations in detecting rectal disease, proctitis cannot be assessed by IUS as an alternative to sigmoidoscopy. While FC has been shown to be useful for follow up of proctitis during treatment with mesalamine suppositories 8 weeks after treatment, the absolute levels of FC in ulcerative proctitis are low [118]. Transrectal endosonography studies show that mucosal thickness correlates with endoscopic disease activity and a decline in bowel wall thickness, which can be determined a few weeks after treatment in patients with active UC [119].
No study has compared the combination of different parameters such as IUS plus FC in active UC, even though it is conceivable that combinations might enhance sensitivity. MR colonography (MRC) can also assess inflammation with relatively high accuracy. In the largest series of 50 patients who underwent both MRC and endoscopy, the segmental simplified MRC index strongly correlated with the modified Baron score ($r=0.81$, $P<0.001$). MRC was also able to detect endoscopic inflammation and severe lesions with high diagnostic accuracy (sensitivity 87% and 83%, specificity 88% and 82%, area under the curve 0.95 and 0.91, $P<0.001$, respectively). MRI may provide useful information on wall thickening, edema, polyps, and extraluminal complications [120-122]. MRI, especially when implemented with diffusion-weighted sequences, has high diagnostic accuracy in detecting active inflammation. Oussalah et al. investigated 35 patients with UC and reported a sensitivity and specificity of 89.47% and 86.67%, respectively [123]. Moreover, the accuracy of the diffusion-weighted imaging hyperintensity for detecting colonic inflammation was greater in UC than in CD ($P=0.004$).

**Statement 2.1.2.1. ECCO-ESGAR Diagnostics GL (2018)**

Clinical and biochemical response to treatment of Crohn’s disease (CD) should be determined within 12 weeks following initiation of therapy [EL2]. Endoscopic or transmural response to therapy should be evaluated within 6 months following initiation of therapy [EL5].

**Statement 2.1.2.2. ECCO-ESGAR Diagnostics GL (2018)**

Endoscopic or cross-sectional reassessment in CD should be considered in cases of relapse, persistent disease activity, new unexplained symptoms, and prior to switch of therapy [EL5].

**Mucosal healing**

There is no reference standard for determining therapeutic success in CD. Clinical symptoms as scored by the CD activity index (CDAI) are not a reliable measure of the underlying inflammation. An increasing body of evidence suggests that MH may change the natural course of CD by decreasing relapse rates, hospitalization rates, and the need for surgery [124-126]; as such evaluation should be aimed at detecting this endpoint, or at least assessing a reliable surrogate marker of MH. MH can be directly visualized endoscopically. Cross-sectional imaging and noninvasive serological and faecal surrogate markers may however provide an indication, especially important when assessing parts of the bowel that are difficult to reach endoscopically.

The time interval of when to evaluate MH endoscopically can be inferred somewhat from trial data. However, studies have seldom been designed to directly evaluate the best point for reassessment, and as such inferences regarding optimal timing for re-evaluation must be taken with care. Any recent change in therapy must also be considered. For example, it is recognized that the anti-
The degree of mucosal inflammation may differ between segments of the digestive tract [128]; the need for panenteric evaluation remains to be determined. In a retrospective analysis of the SONIC trial, CDAI scores and CRP values at baseline and at week 26 were analysed from 188 CD patients who had evaluative ileocolonoscopy with evidence of mucosal ulceration at baseline [129]. Half of the patients treated with azathioprine or infliximab (or both) in clinical remission had endoscopic or CRP evidence (or both) of residual active CD, whereas other patients with endoscopic and CRP normalization had persistent clinical symptoms. In a retrospective study of 201 patients with CD, the predictors of medium-term clinical efficacy and MH during adalimumab therapy were evaluated [130]. Clinical efficacy and normalised CRP at week 12 were associated with medium-term clinical efficacy and mucosal healing during adalimumab therapy, whereas need for combined immunosuppression at induction and smoking status were predictors for non-response. Thus, correlation between CRP and MH is variable. Several studies indicate that FC correlates well with colonic inflammation in CD and might therefore be used as a surrogate marker [62, 112]. Importantly, although initial studies suggested that FC may be less sensitive in isolated small-bowel disease, a recent meta-analysis demonstrated that the diagnostic yield of FC is significant for detection of active disease in the small bowel, with a negative predictive value (NPV) of 90% for the cut-off value of 50 µg/mL [62].

Transmural healing – Role of MRI, CT, and IUS

There is no reference standard for IBD activity and any kind of diagnostic modality (including endoscopy, MRI, laboratory parameters, or IUS) can only be used as surrogate markers in this situation. CD is a transmural process, thus full-thickness bowel healing or remodelling could be important endpoints.

Various studies have assessed the value of cross-sectional imaging techniques for therapeutic monitoring in CD affecting the small and large bowel. These studies assessed IUS [131-136], CT [137], or MRI [138-140].

The role of IUS as a noninvasive and inexpensive imaging modality for determining the treatment response of transmural inflammation in CD has been evaluated in different studies. The utility of IUS
for assessing activity and drug response has been compared with colonoscopy [116], with high concordance (weighted $k$ between 0.76 and 0.90). For example a prospective study performed on 24 consecutive patients with CD used IUS to assess changes induced by anti-TNF therapy and its relationship with clinical and biological response [141]. Parameters were measured one week prior to induction treatment and two weeks thereafter. Anti-TNF therapy led to a significant reduction in bowel wall thickness ($P=0.005$) and Doppler flow ($P=0.02$), leading to the disappearance of IUS changes in 50% of the patients. However, sonographic normality was only achieved in five out of 17 patients (29%) with a clinical and biological response and could not differentiate between those with and without clinical and biological response ($P=0.27$). A more recent prospective trial evaluated IUS features in patients with CD after treatment with biologics using ileocolonoscopy as a reference standard [142]. In this trial, normalization of the IUS parameters could be observed in 62.8% of the patients, with a significant correlation compared to ileocolonoscopy ($k=0.76$; $P<0.001$). Some authors suggest that CEUS might be useful to determine treatment outcome shortly after initiating treatment with biologics [133]. In a study on 133 CD patients, transmural healing could be observed in approximately 25% of patients [134]. Most of the patients received anti-TNF therapy. In a paediatric CD study, 32 patients were included and followed up by IUS and ileocolonoscopy 9 to 12 months after treatment initiation. Patients with MH showed a significant decrease of bowel wall thickness and disease extension [135]. In a prospective multicentre longitudinal study of 51 patients with active CD, all patients underwent a clinical assessment and sonographic examination at baseline, 12 weeks after treatment initiation, and after 1 year of treatment [136]. Improvement at 52 weeks was more frequent in patients with improvement at the end of induction (12 weeks) compared with patients who did not improve (85% versus 28%; $P<0.0001$). The authors concluded that sonographic response after 12 weeks of therapy predicts 1-year sonographic response. A large multicentre trial including 243 patients from 50 centres in Germany has recently been conducted to determine the role of IUS for monitoring treatment response [132]. In this trial, CD patients with an acute disease flare received anti-inflammatory treatment. Almost all sonographic parameters determined during IUS (including bowel wall thickness, vascularization parameters, fibro-fatty proliferation) showed a highly significant decrease ($P<0.001$ in all groups) at different sites. Interestingly, reduction of bowel wall thickness was more pronounced in the colon compared with the ileum. Improvement of ultrasound parameters correlated with laboratory parameters such as CRP [132]. Based on current studies, IUS seems to be a valuable method to determine transmural healing in CD with bowel wall thickness and vascularization appearing to be the most relevant parameters [143].

The value of CT was assessed in a retrospective North American study on 63 infliximab-treated patients with CD [137]. Twenty-one of 105 lesions (20%) were colonic. Poor-to-fair correlation was found between CT enterography features of response and improved clinical symptoms ($k=0.26$), improved endoscopic appearance ($k=0.07$), and reduction of CRP ($k=0.30$). When comparing responders (complete and partial) with nonresponders, only the presence of the ‘comb sign’ on the index CT enterography was predictive of radiologic response ($P=0.024$). Even though CT in principle might be a suitable method to determine disease activity in CD, it should be noted that CT, due to radiation safety, should not usually be used for monitoring disease activity if MRI or IUS are available.
In terms of responsiveness and reliability, different studies have shown that MRI has a high accuracy for monitoring therapeutic responses using endoscopy as a reference standard [138-140]. In a recent study, 48 patients with ileocolonic CD were prospectively evaluated with MR enterography in comparison with ileocolonoscopy [138]. MR enterography determined ulcer healing with 90% accuracy and endoscopic remission with 83% accuracy. The mean CD endoscopic index of severity (CDEIS) and magnetic resonance index of activity (MaRIA) scores significantly changed at week 12 in segments with ulcer healing, based on endoscopic examination (CDEIS, 21.28±9.10 at baseline versus 2.73±4.12 at 12 weeks; \( P<0.001 \) and MaRIA, 18.86±9.50 at baseline versus 8.73±5.88 at 12 weeks; \( P<0.001 \)). The authors concluded that the MaRIA score is a valid, responsive, and reliable index assessing response to therapy in patients with CD.

In a retrospective study with 50 patients MRI inflammation scores during anti-TNF therapy improved in 29 of 64 lesions (45.3%), remained unchanged in 18 of 64 lesions (28.1%), or deteriorated in 17 of 64 lesions (26.6%) over time. In the anti-TNF responder group, the mean intestinal inflammation score of all lesions improved from 5.19 to 3.12 (\( P < 0.0001 \)). The mean inflammation scores in stenotic lesions in anti-TNF responders also improved significantly, from 6.33 to 4.58 (\( P = 0.01 \)). In contrast, the mean inflammation scores did not change significantly (5.55-5.92, \( P = 0.49 \)) in nonresponders. Diagnostic accuracy of anti-TNF response on MRI was 68% [139]. The authors conclude that MRI can be used to guide the optimal use of TNF antagonists in daily clinical practice.

In a prospective single center trial with 27 patients treated with anti-TNF (infliximab or adalimumab) the mean SES-CD and MaRIA scores significantly changed at week 26 (SES-CD: 14.7±8.9 at baseline vs. 4.4±4.6 at 26 weeks - \( p<0.001 \); MaRIA: 41.1±14.8 at baseline vs. 32.8±11.7 at 26 weeks - \( p<0.001 \)). The overall MaRIA correlated with endoscopic score and with clinical activity (CDAI) both at baseline and at week 26 (\( p<0.05 \)). The authors conclude that the MaRIA has a good correlation with SES-CD, a high accuracy for prediction of endoscopic mucosal healing and is a reliable indicator to monitor the use of TNF antagonists in patients with CD [140]. meta

In a systematic review and -analysis to identify MRE variables used to describe inflammation and damage wall enhancement, mucosal lesions and wall T2 hyperintensity were the most consistently useful for inflammation (most sensitivities >80% and specificities >90%) [144].

In addition, in a retrospective analysis of 150 CD patients having either had a pre- and post-therapy CTE or MRE radiological response to medical therapy was associated with significant reductions in long-term risk of hospitalization, surgery, or corticosteroid usage among small bowel CD patients [145].

As MR enterography and IUS appear to be of similar value for monitoring transmural healing in CD during treatment, which imaging modality to use depends on local availability and expertise.

**Video-capulse endoscopy**
As endoscopic access of the small bowel is more difficult, response to treatment should either be determined by IUS or MR enterography or by capsule endoscopy. The superiority of small-bowel capsule endoscopy (SBCE) compared with other imaging modalities to determine small-bowel disease in CD has been described in different studies [146].

Recent clinical trials have evaluated the potential role of SBCE for assessment of MH in the small bowel [147-149]. These trials used quantitative scores such as the Lewis score [150] or the capsule endoscopy CD activity index (CECDAI) analogous to the application to ileocolonoscopy of the CDEIS or the simple endoscopic score for CD. In a case-control study, 40 patients with known or suspected CD were included and underwent SBCE [147]. When patients achieved clinical response (after at least a month of treatment) they underwent a second SBCE, with evaluation of the same parameters. The numbers (mean±SEM) of large ulcers before and after treatment were 8.3±1.4 and 5±0.8, respectively (mean difference 3.3±1.2, 95% confidence interval [CI] 0.8–5.9; \( P=0.01 \)). The other variables did not improve significantly. In another study, the CECDAI index was used to assess ileitis severity. All parameters were reassessed at week 52. In total, 108 capsule procedures were performed on 43 patients. Based on the CECDAI, 39 patients (90%) exhibited active small-bowel CD at baseline with 28 patients (65%) undergoing assessment at 52 weeks. In total, 12 patients (42%) achieved complete MH and deep remission at the 52-week assessment (95% CI -0.62 to -0.22; \( P<0.0001 \)) [148]. SBCE has a significant impact on disease management; in the largest retrospective series of patients with established CD that were evaluated with SBCE, a change in management was suggested in 52% of 187 patients [60].

**Statement 2.1.2.3. ECCO-ESGAR Diagnostics GL (2018)**

In the absence of credible evidence to support the best modality to assess response to treatment in upper GI disease of CD, endoscopy is recommended as the preferred method [ELS]

Data on imaging in upper GI CD and in particular on monitoring disease is sparse and sizeable series are unavailable, with essentially absent data for the stomach. Cross-sectional imaging may reveal ulcers or strictures in oesophageal CD but superficial lesions are difficult to detect, underscoring the importance of endoscopy in the diagnosis of oesophageal CD. Endoscopy with tissue biopsy is useful to exclude other common oesophageal disorders. The most commonly described findings on endoscopy include aphthous ulcers, superficial erosions, and late-stage stricture development and cobblestoning of the mucosa [151, 152]. One study discussed the application of various methods to diagnose various inflammatory conditions of the oesophagus [153].
Although IUS and MRI seem to be feasible tools to determine disease activity of CD in the duodenum and stomach, there are no convincing data that prove their value in disease monitoring. Upper GI involvement should therefore be primarily monitored by the reference standard endoscopy.

Statement 2.1.2.4. ECCO-ESGAR Diagnostics GL (2018)

Extramural complications in CD (such as fistulae and abscesses) should be monitored by cross-sectional imaging, including intestinal ultrasound (IUS) [EL2] or MRI [EL2] (or both) in combination with clinical and laboratory parameters [EL5]

While a variety of studies have shown good sensitivity and specificity of cross-sectional imaging to assess fistulae and abscesses, there are only few studies that address the follow up of these extramural complications after treatment. The sensitivity of cross-sectional imaging modalities such as MRI, IUS, and CT to determine extramural complications has been shown to be high in a recent meta-analysis, with sensitivity between 84 to 93% and specificity between 90 to 93%, as discussed above [81, 154]. Although CT is accurate for follow up of mural and extramural complications in CD patients, CT is not recommended for monitoring patients with active disease under treatment due to radiation safety [155]. Although the dose can be reduced substantially with state-of-the-art low-radiation-dose CT scanners, the use of nonionizing radiation techniques is preferable, considering the usually young age of these patients. Thus, CT should be used judiciously, ideally only in the emergency setting and if IUS and MRI are unavailable.

Statement 2.1.2.5. ECCO-ESGAR Diagnostics GL (2018)

Perianal CD should be reassessed by clinical evaluation in combination with endoscopic examination of the rectum plus MRI [EL1]. Transrectal ultrasonography (TRUS) in the absence of anal stenosis [EL1] or transperineal ultrasonography (TPUS) [EL2] might be used instead of MRI

Evaluation of perianal CD and fistula closure is primarily achieved with clinical evaluation. The definition of fistula healing varies in the literature and there is no consensus on when a first or definitive evaluation of fistula healing should be performed [156]. The perianal disease activity index (PDAI) [157] is a clinical scoring system that has been used and validated in clinical studies both at diagnosis and to measure treatment response. Fistula drainage assessment has been used in several clinical trials of medical therapy [158-160], but is very much investigator-dependent and has not been validated in large studies. A single retrospective study has evaluated the PDAI scoring system, where high scores predicted short-term surgical outcome, but this has not since been validated [161].
MRI classifications of fistula severity have been proposed, such as the system published by Van Assche et al. [162]. Thus far, this system is of limited use outside of clinical trials. MRI is increasingly used to assess fistula healing, particularly during medical therapies [162-164]. Various MRI classifications have been proposed, including the Van Assche score [162], which considers the number of fistulae, localization, extensions, T2 hyperintensity, abscesses, and rectal involvement. Assessment of dynamic contrast enhancement has also been proposed as a means to monitor fistula activity [165]. It has been shown that fistulae may reopen after therapy cessation and studies using MRI findings as a more stringent endpoint of deep fistula healing suggest that MRI [162, 164, 166] and endoanal ultrasound [167, 168] may be useful for identification of fistulae that show external closure but retain an internal fistula tract. This suggests that imaging assessment of deep healing is superior to simple clinical evaluation, although long-term comparative studies are lacking.

Despite the lack of relevant studies evaluating the role of MRI for the specific assessment of patients during and after therapy, several comparative studies have been performed evaluating ultrasound and MRI in perianal fistula diagnosis in CD. In most of these studies, MRI seems to be the method of choice. Schwartz et al. compared examination under anaesthesia (EUA), MRI, and transrectal ultrasonography (TRUS) and demonstrated a diagnostic accuracy of 91%, 87%, and 91%, respectively [169]. Buchanan et al. performed a large prospective clinical trial comparing preoperative digital rectal examination, endoscopic ultrasound and body-coil MRI for the preoperative assessment of fistulae in ano. According to their results, MRI was superior to both methods for abscess detection and accuracy in fistula classification (90% of patients correctly classified by MRI, 81% by TRUS, and 61% by EUA) [170]. In a recent meta-analysis, the sensitivity between MRI and TRUS regarding sensitivity to determine perianal CD was 87% for both imaging modalities, while specificity was 69% versus 43%, respectively [171]. A recent consensus suggested a combination of different imaging modalities for diagnostic use during perianal CD [172].

MRI may therefore be slightly superior to TRUS for determining perianal disease activity. However, use of the adequate imaging modality also depends on local availability and expertise.

If MRI is not available and TRUS is either not available or unfeasible due to pain, transperineal ultrasonography (TPUS) is an alternative, although its sensitivity is lower than TRUS. In a recent study investigating 46 patients with perianal CD, 53 fistulae detected by TRUS were correctly classified by TPUS in 45 cases, reaching a sensitivity of 84.9% [173].

**Statement 2.1.2.6. ECCO-ESGAR Diagnostics GL (2018)**
Therapeutic drug monitoring might be beneficial in CD and UC in patients with nonresponse to thiopurines [EL3] or anti-TNF therapy [EL2]. Drug level monitoring is mandatory during treatment with calcineurin inhibitors [EL2].

Primary nonresponse and secondary loss of response are common problems during anti-TNF therapy. Loss of response (LOR) to anti-TNF has been shown to be as high as 20 to 40% after the first year of treatment [174] and about 10% in the following years.

In a recent study on 247 patients, it was shown that therapeutic drug monitoring by measurement of anti-TNF trough levels and antidrug antibodies in IBD patients with secondary LOR may lead to therapeutic changes in more than 70% of patients [175]. Several studies have demonstrated that low trough levels and detectable antidrug antibodies are associated with LOR [176-178]. In a recent meta-analysis of 22 trials with 3483 patients, it was shown that high infliximab trough levels correlate with good clinical response and low CRP levels [179]. Similar results have been shown for golimumab [180] and adalimumab [181]. Even though the primary endpoint of the TAXIT trial (treatment guidance via infliximab trough level concentration measurements) was not achieved, it was shown that dose escalation in patients with subtherapeutic levels improved clinical response [182]. The optimal trough level concentration in this study was defined as between 3 to 7 µg/mL. A cohort of 60 CD patients treated with adalimumab has been investigated retrospectively [183]. Higher adalimumab trough levels were significantly associated with MH (median 14.7 µg/mL in those with MH versus 3.4 µg/mL in those without; P<0.001). This study suggests that attaining MH alone or a combined outcome of clinical and endoscopic remission is more likely to occur in those patients who achieve an adalimumab trough level of at least 8.14 µg/mL.

In a recent study, primary nonresponse to anti-TNF therapy in patients with severe UC was associated with faecal loss of infliximab [184]. However, the optimal timepoints and cut-off levels for trough level measurements to determine primary nonresponse must still be determined.

Different studies have shown that measurement of thiopurine metabolites, such as 6-MMP and 6-TGN, might be beneficial in patients with suboptimal response to thiopurines. In a recent study, determination of 6-TGN and 6-MMP levels identified patients with reduced compliance in 11% and raised 6-MMP levels in 10%. Treatment improvement could be achieved in 87% of patients after optimizing thiopurine usage [185].

It is likely that as vedolizumab and ustekinumab drug monitoring becomes more easily available, this will also form part of management strategies when treating patients with these agents.
2.2. Monitoring clinically asymptomatic patients

Statement 2.2.1. ECCO-ESGAR Diagnostics GL (2018)

In patients with IBD who have reached clinical and biochemical remission, monitoring is aimed at early recognition of a disease flare [EL5]. The interval of monitoring should be between 3 to 6 months depending upon duration of remission and current therapy [EL5].

Relapse can be detected with FC before clinical symptoms [EL2].

Figure 1 shows a simplified disease progression pathway in IBD from risk factors to irreversible intestinal fibrosis. Of note, the practicality of a given test for IBD monitoring decreases further downstream in the pathway, as the disease becomes more resistant to standard therapy.

The ideal monitoring test is noninvasive, simple to conduct, and easily interpretable. Such a test should detect an imminent disease flare (often undetectable by symptom-based reporting alone) and make provision for proactive treatment optimization (Table 1).

Faecal calprotectin

The utility of FC monitoring in patients with quiescent disease was evaluated in a recently published systematic review [186]. Electronic searches up to April 2016 identified six prospective studies (mostly in UC patients) that met the selection criteria. Since then an additional five prospective
studies in both UC and CD patients were published [118, 187-190].

Two consecutively elevated FC levels were the best predictor for clinical relapse, but this was investigated systematically in only one study [191]. In one of the more recently published studies, patients with both UC and CD provided faecal samples every third month and were prospectively followed until the first clinical relapse [188]. This study revealed that FC levels start rising approximately 3 months before a relapse becomes clinically apparent and confirmed the observations of the aforementioned systematic review. These findings support the biological implausibility that a single FC measurement at baseline can predict the clinical course over a 12-month period, as suggested in a meta-analysis [192] and more recently by Theede et al. [193].

Currently, there is no consensus on the ideal cut-off point for FC monitoring. In clinical trials where response to a new treatment is monitored, a low cut-off point (e.g. 100 μg/g) is frequently used to demarcate the upper limit of the normal FC range. Conversely, in real-life studies, a higher cut-off point is advocated (e.g. 250 μg/g) as an action threshold for adjusting treatment [194-197]. A prospective evaluation of a monitoring strategy is needed, namely, a planned and organized system of repeated FC assessments and subsequent decisions about starting, modifying, or de-escalating therapy, as has been part of the recently published CALM study [198].

A general construct for FC-based disease monitoring in patients with IBD is shown in Figure 2, which illustrates the four phases of disease monitoring [199, 200]. Repeated FC measures are used to longitudinally track changes in a patient’s condition over time. In phase I, IBD is suspected, but neither endoscopically confirmed nor treated. In phase II, induction therapy is introduced to achieve disease control, resulting in patient response. Phase III begins with disease remission with continuation of maintenance therapy. The goal of monitoring in this phase is to detect deviations from the target range, indicating the start of phase IV. In phase IV, therapy is adjusted to re-establish disease control and bring FC levels back to the target range.
When the FC concentration is in the target range, the patient is reassured and advised to retest in 3 months. When the FC concentration is in the action range, the treatment plan is adjusted and retesting is advised for the next month. In the uncertain range, a test interval of 1 month is advised before progressing to a treatment decision.

C-reactive protein

Serum CRP is an acute-phase reactant that has been used in clinical practice for many years as a general measure of inflammation. In a meta-analysis of cohort and case-control studies that compared the diagnostic accuracy of CRP (index test) with endoscopy (reference standard) in patients with symptomatic IBD, a CRP concentration of ≥5 mg/L appeared to have a high specificity for detecting endoscopic disease activity [111]. However, the sensitivity was very poor and a negative test does not exclude the presence of a flare. Almost two thirds of the asymptomatic patients with normalized CRP still had active endoscopic lesions, and consequently an isolated fall in CRP was insufficient reassurance of endoscopic remission [201]. Repeated CRP measurements in the detection of early postoperative recurrence of CD [202] or in the follow up of small-bowel CD [203] are inferior to repeated FC measurements.
Statement 2.2.2. ECCO-ESGAR Diagnostics GL (2018)

Asymptomatic patients with abnormal biochemical parameters may have an imminent disease flare. After excluding infection, endoscopic or cross-sectional imaging (or both) should be performed [ELS]

Capsule endoscopy

Recent prospective studies have shown that stool markers such as FC are useful in monitoring inflammation in the small bowel. Increased FC levels with negative findings on conventional endoscopy should trigger further investigations into the presence of active small-bowel disease [204]. Small-bowel CD is in many cases located proximal to the terminal ileum and therefore inaccessible to conventional ileocolonoscopy. In a considerable proportion of asymptomatic patients with CD, previously unknown new proximal involvement and progression to stricturing or penetrating disease was demonstrated with capsule endoscopy [61], leading to modifications in the original Montreal classification and consequently to treatment escalation [205]. In a prospective observational cohort of patients with asymptomatic or mildly active small-bowel CD, tolerance and preference to MR enterography versus capsule endoscopy were compared. Pre-examination and procedural discomfort was perceived more favourable in capsule endoscopy. The superior tolerability of capsule endoscopy, along with diagnostic features, should be considered when choosing between these two modalities for long-term follow up [205]. A negative FC result in an asymptomatic CD patient should deter the clinician from using additional small-bowel imaging techniques [204].

MR enterography

MR enterography is not a suitable technique for early recognition of disease recurrence, since aphthoid ulcerations cannot be assessed. As disease severity progresses, MR enterography manifestations become more apparent. Several studies have evaluated the ability of MR enterography to quantify therapeutic response to immunosuppressive therapy, especially in children [206].

Intestinal ultrasound

IUS is a noninvasive, widely available technique that does not use ionizing radiation and is well accepted and tolerated by patients. Most parts of the large bowel (with the exception of the rectum) and major parts of the small bowel (with the exception of the proximal jejunum) can be visualized by
The advantages of IUS include rapid evaluation of bowel wall thickness and direct visualization of bowel vascularization and motility [88, 207, 208]. The role of this technique in monitoring patients with asymptomatic CD or UC is not yet clear. More is known about the role of IUS in monitoring response to treatment in CD patients. In a prospective trial that followed 234 CD patients with bowel wall alterations in the terminal ileum or in the colon, follow-up every three month showed significant improvements in nearly all ultrasound parameters [132]. There is good concordance between ultrasound and MR enterography for disease location and activity, and fewer technical difficulties with IUS [209].

**Statement 2.2.3. ECCO-ESGAR Diagnostics GL (2018)**

*Before de-escalation or withdrawal of maintenance IBD therapy, it is necessary to assess disease activity using a combination of clinical and biochemical markers and endoscopic and/or cross-sectional imaging, balancing the risks and benefits of withdrawal [EL5]*

In a recent meta-analysis of 18 studies, stopping immunomodulatory monotherapy after a period of remission was associated with approximately 75% of patients experiencing a relapse within 5 years after therapy discontinuation [210]. Approximately 50% of patients who discontinued anti-TNF therapy after combination therapy in this systematic review maintained remission 24 months later, but the proportion decreased over time [210]. Similar results have been reported in other meta-analyses [211, 212]. The factors that predict relapse after discontinuation of therapy remain controversial.

In a placebo-controlled study by the GETAID group that included 83 patients in clinical remission under azathioprine, neither the presence of ulcerations nor a CDEIS > 0 at ileocolonoscopy before azathioprine discontinuation were predictive of clinical relapse [213]. In contrast, in another GETAID trial, Louis et al. assessed the risk of clinical relapse after discontinuation of infliximab in 109 patients with CD who were in clinical remission under combined maintenance therapy with infliximab and an immunomodulatory agent [214]. In their multivariate analysis, the absence of MH was among the factors strongly associated with an increased risk of clinical relapse after infliximab withdrawal (hazard ratio 2.6). In this study, immunosuppression with azathioprine or methotrexate was continued after infliximab withdrawal. In a recent meta-analysis, the relapse rate 1 year after discontinuation of anti-TNF therapy was 42%, which decreased to 26% when endoscopic remission was also required [211]. Assessment of endoscopic activity in patients with quiescent CD is recommended before discontinuation of treatment is considered.

2.3 Monitoring clinically symptomatic patients

Statement 2.3.1. ECCO-ESGAR Diagnostics GL (2018)

All patients with a suspected new flare of IBD should be investigated for infection, including exclusion of *Clostridium difficile* infection [EL3]

Bacterial infection and *Clostridium difficile* should be excluded in all patients. Diagnostic workup is recommended according to test availability and local practice. Available tests include glutamate dehydrogenase antigen and toxin A/B enzyme immunoassays, bacterial cultures, cytotoxicity assay, and nucleic acid amplification technology tests.

This is particularly important in patients with colonic disease where the diagnostic yield is higher; in one series of paediatric patients with UC (N=354 stool tests), 1.8% of tests were positive for *Salmonella* serotype Typhi and 13.6% were positive for *C difficile* toxin [215]. Patients with CD have comparatively lower rates of *C difficile* infection [216].

In UC, *C difficile* is associated with poorer outcome, including increased colectomy rates [217] and increased postoperative complications [218] [219]; detection is thus of direct clinical relevance. Additional interrogation of faeces with PCR should not be performed routinely as there is a high rate of detection of bacteria that may not be of clinical significance, even in healthy controls [220].
Parasitic infections are found in about 12% of patients with UC who reside in endemic areas [221]. If travel history is suggestive, stool examination for ova cysts and parasites and *Strongyloides* serology should be performed before therapy is escalated. Local protocols regarding testing and transport of stool samples should be followed. Further guidance on management of opportunistic infection can be found in the second European evidence-based consensus on the prevention, diagnosis, and management of opportunistic infections in inflammatory bowel disease [26].

**Statement 2.3.2. ECCO-ESGAR Diagnostics GL (2018)**

*Cytomegalovirus (CMV)* should be tested in immunosuppressant-resistant UC as CMV is associated with adverse outcomes, including reduced efficacy of therapy and increased colectomy rates [EL3]

A recent meta-analysis revealed that *cytomegalovirus* (CMV) infection in IBD may be associated with longer disease duration, reduced efficacy of corticosteroid therapy, and increased colectomy rate [222]. Corticosteroid and thiopurine exposure are associated with reactivation of latent CMV [223]. However, tissue damage following exposure to immunomodulators is rare [224]. Anti-TNF agents and cyclosporine also do not appear to be associated with adverse outcomes in CMV-positive patients [225]. Therefore, the ECCO guidance on opportunistic infections recommends that testing for CMV should be reserved for steroid-resistant disease [26].

CMV disease is most commonly assessed via detection of CMV DNA through PCR or immunohistochemistry of tissue biopsies and blood. The second European evidence-based consensus on opportunistic infection in IBD provides more detailed information on the diagnosis and management of CMV infection [26].

**Statement 2.3.3. ECCO-ESGAR Diagnostics GL (2018)**

Colonoscopy is the modality of choice to assess disease activity of symptomatic colonic CD or UC [EL5]. Cross-sectional imaging is complementary to assess phenotype [EL2] and may be used as an alternative to evaluate disease activity. Sigmoidoscopy should be considered in UC if symptoms suggest an acute severe flare

Ileocolonoscopy provides direct mucosal visualization of the colon and terminal ileum and allows histological assessment and therapeutic intervention. As such it is the gold standard investigation of large-bowel disease.
If assessment of disease location or behaviour is not necessary, FC can be used to evaluate activity from the colon to the small bowel [226],[227],[228],[204],[62],[229]. Studies have shown good correlation (r>0.8) with endoscopic disease activity in both CD and UC [230],[231].

If acute severe UC is suspected, endoscopic evaluation should be limited to flexible sigmoidoscopy as discussed previously in this guideline.

MR enterography [232],[233],[234],[235],[236],[237] of the colon, capsule endoscopy [238],[239],[240], and IUS [115] can also be considered for assessment of disease extent and phenotype in individuals reluctant to endoscopic evaluation. In a UK multi-centre trial US had superior sensitivity than MRE for colonic disease presence in newly diagnosed patients (67% vs. 47% respectively) [87].

**Statement 2.3.4. ECCO-ESGAR Diagnostics GL (2018)**

**Symptomatic small-bowel disease can be investigated with MR enterography, IUS, and/or small-bowel capsule endoscopy (SBCE) [EL2]**

MR enterography, IUS, and SBCE are all sensitive and specific investigations of symptomatic small-bowel disease. The decision on which investigation is ‘first line’ is based upon local availability and expertise.

MR enterography allows assessment of the small bowel without radiation exposure [241]. The presence of wall oedema, contraction frequency [242], ulcers, and extramural signs such as fat stranding and lymphadenopathy make MR enterography somewhat informative of whether the abnormalities detected are more inflammatory or fibrotic [242],[243],[244],[245]. However, it should be noted that no imaging modality can fully assess whether a stricture is inflammatory or fibrotic in nature. MR enterography is also safe and well tolerated in paediatric populations [246],[247],[248]. A recent meta-analysis of 27 studies (19 included in pooled analysis) showed MRI to have a sensitivity of 0.88 (95% CI 0.86–0.91) and a specificity of 0.88 (95% CI 0.84–0.91) [249]. The studies included both MR with oral contrast solution (MR enterography) or contrast administered by nasojejunal tube insertion (MR enteroclysis). MRI is perhaps superior to IUS in assessing disease extent [86] and leads to changes in clinical management following investigation [250]; MRI increases scores of disease location (L) and disease behaviour (B) of the Montreal classification in over 20% of patients [251].
MR enteroclysis is not significantly more sensitive or specific than MR enterography [252]. MR enteroclysis is also less well tolerated than MR enterography [253] and requires minimal radiation exposure for fluoroscopic nasojejunal placement [254]. Accordingly, MR enteroclysis is not routinely recommended.

IUS may be available immediately within the clinical setting; if this investigation is sufficient to confirm active disease it may preclude the need for further investigation. The sensitivity and specificity of IUS can be enhanced with contrast studies. Small intestine contrast ultrasound (SICUS) entails administering oral contrast and enables a greater rate of detection of small-bowel lesions than by standard IUS [255],[256] and in particular enables greater detection of strictures and associated dilatation. SICUS shows sensitivity and specificity comparable with MR enterography and CT enterography [257],[258],[259]. In one study, SICUS was shown to be more sensitive in the proximal small bowel (92% versus 75%), similar within the proximal and mid ileum, and less specific within the terminal ileum [260]. One study showed SICUS to be more sensitive and specific than CT enteroclysis [261]. The rates of detection of small-bowel complications (such as strictures) are comparable with MR enteroclysis [258]. CEUS may facilitate differentiation between inflammatory and fibrotic strictures [262]. In the recently published METRIC trial both MRE and IUS had a high sensitivity for detecting small bowel disease presence. However, the sensitivity of MRE for small bowel disease extent (80% [95% CI 72-86]) and presence (97% [91-99]) were significantly greater than that of IUS (70% [62-78] for disease extent, 92% [84-96] for disease presence); a 10% (95% CI 1-18; p=0.027) difference for extent, and 5% (1-9; p=0.025) difference for presence [87].

Most studies show the diagnostic accuracy of SBCE to be comparable with MR enterography, CT enterography, and IUS in CD [263],[264],[265],[266],[56, 267], although a 2017 meta-analysis demonstrated superior detection of proximal small-bowel disease compared with MR enterography (odds ratio [OR] 2.79, 95% CI 1.2–6.48) [56]. This is in comparison with MR enterography, CT enterography, barium studies, and IUS [89]. Clinically, the use of SBCE is associated with earlier escalation of therapy [268]. However, the benefits of this investigation are somewhat offset by a small risk of capsule retention; even with use of patency capsule in patients deemed to be at risk, the rates of capsule retention range from 1.5 to 2.1% [60]. The outcome of the retained capsule varies between studies; approximately 85% are asymptomatic and 15% result in partial or complete small-bowel obstruction. The latter generally requires surgical management. The former can sometimes be retrieved with small-bowel enteroscopy or managed conservatively [269]. Routine use of a patency capsule has not been shown to reduce the risk of retention in the absence of risk factors. Patients who benefit from patency capsules include those with stricturing or penetrating disease phenotypes [270]. Cost analyses suggest that SBCE is cost effective [271] and frequently leads to changes in therapy [272].

Barium studies, in particular barium follow through, are still used in some centres for suspected active small-bowel CD [273], [274]. However, sensitivity and specificity are less than that of MR enterography, IUS, or SBCE. Furthermore, radiation exposure also makes barium studies less
appealing [275]. This is particularly true in paediatric assessment [276]. Accordingly, ECCO-ESGAR discourages barium studies unless local facilities preclude alternatives.

CT should largely be reserved for the emergency setting due to radiation exposure. However, low-radiation CT enterography yields results comparable with full-dose CT when evaluating CD. Accordingly, low-radiation CT enterography may be an alternative when local resources preclude alternatives or in older patients where radiation exposure is of less concern. When considering the efficacy of CT, the diagnostic yield of CT enterography is similar to that of MR enterography [277],[278],[80]. Indeed, several studies comment that CT yields images of higher spatial resolution [279],[280],[281] and that there is greater agreement between radiologists when interpreting CT [277]. CT is often the only cross-sectional abdominal imaging modality available outside of standard working hours and as such is widely used in the emergency setting. CT has a high detection rate of complications, including perforation, strictures, and abscesses [281].

Studies of positron emission topography (PET) are limited. At present, PET does not appear to detect significantly more lesions than CT enterography [282] or MR enterography alone [283]. Leukocyte scintigraphy has been shown to detect inflammatory lesions not otherwise known prior to laparotomy. However, there is insufficient evidence to routinely include this test in clinical practice [284].

Noninvasive evaluation of symptomatic IBD includes measurement of blood and stool inflammatory markers and measurement of parameters indicative of malabsorption. The use of noninvasive markers to assess disease activity is largely covered elsewhere. In brief, FC is a more sensitive marker of disease activity than haemoglobin, CRP, or albumin [285],[286]. In symptomatic disease, FC can be used to evaluate activity from the colon to the small bowel [226],[227],[228],[204],[62],[229]. Studies have shown good correlation (r>0.8) with endoscopic disease activity in both CD and UC [230],[231]. One of the main drawbacks of indirect markers is their limited information on disease phenotype and potential complications.

**Statement 2.3.5. ECCO-ESGAR Diagnostics GL (2018)**

**Balloon-assisted enteroscopy can be used for diagnostic evaluation or endoscopic intervention (or both) throughout the small bowel [EL3]**

Balloon-assisted enteroscopy allows direct mucosal visualization of the entire small bowel. Unlike other imaging modalities, balloon-assisted enteroscopy also enables taking of biopsies, therapeutic intervention throughout the small bowel [287],[288],[289], and interventions to manage bleeding.
One study showed a change in management in 75% of patients who underwent this investigation [290]. However, this examination is time consuming and requires patient sedation. The risk of perforation is 0.12% without therapeutic intervention but 1.74% with therapeutic intervention, the majority of which occurred after stricture dilatation [291]. Bleeding occurs in approximately 2.5% [292], although one series demonstrated four out of six significant bleeds occurring post polypectomy [293]. It is worth noting that real-world data on both the benefits and complications are skewed by selection bias, as at present this test is usually reserved for patients where other imaging modalities have been inconclusive or in scenarios when therapeutic intervention is a key aim.

**Statement 2.3.6. ECCO-ESGAR Diagnostics GL (2018)**

**Malabsorption parameters should be assessed at regular intervals in all patients with IBD [EL5]**

Nutritional deficiencies are frequently associated with symptomatic IBD. The reason for this is two-fold. Firstly, the discomfort and anorexia associated with disease flares preclude adequate intake. Secondly, inflammatory or fibrotic change to the bowel directly hinders absorption.

In all patients with IBD, weight should be recorded at each clinic review with the aim of early dietetic support when unintentional weight loss is noted. Anaemia is common and should be screened for in all IBD patients; this topic is covered in full in chapter 1 of this guideline. Patients with symptoms suggestive of active disease should be screened for anaemia every 3 months. Initial screening should include complete blood count, ferritin, and CRP. There is no evidence on optimal screening intervals for any of the parameters used for malabsorption. Common practice in patients with small-bowel disease or prior resection is to measure vitamin B12 and folic acid every 3 to 6 months. Judicious care must be taken when interpreting ferritin results in symptomatic patients; the ECCO anaemia guideline recommends ferritin values of up to 100 µg/L may still be consistent with iron deficiency in active disease, especially with a transferrin saturation of <20%. If low haemoglobin is confirmed, a more extensive workup should be undertaken as per the anaemia guideline.

Low albumin is common in active IBD as it is an acute phase protein. Active IBD itself may lead to malabsorption, and low albumin in IBD may correlate with nutritional status. However, the use of albumin as a direct marker of malabsorption is tenuous. In a meta-analysis of 63 studies, albumin did not correlate with nutritional status in calorie-restricted but otherwise healthy individuals [294]. Longitudinal follow up of serum albumin in patients with anorexia nervosa and in healthy controls also failed to yield significant differences [295]. As such, albumin is not an appropriate test for malabsorption and ECCO does not recommend albumin measurements for this reason.
Low vitamin D has been observed in between 16 to 95% of IBD patients, depending upon the study [296],[297]. Deficiency is associated with active disease, female gender, and non-Caucasian ethnicity, with one recent study suggesting higher prevalence in CD [298]. A retrospective analysis has also linked low vitamin D with more frequent flares and lower quality-of-life scores [299]. Unfortunately, prospective follow up after supplementation does not show a clear beneficial impact in disease course [300]. Nevertheless, ECCO suggests measuring vitamin D in symptomatic patients, then re-evaluating after treatment to verify that levels are replete.

Other micronutrient deficiencies to be considered in IBD patients include vitamin K, selenium, vitamin A, vitamin C, zinc, vitamin B6, and vitamin B1 [301],[302]. All patients with symptomatic IBD do not routinely require evaluation of all of the above. However, testing should be considered in patients with small-bowel CD, in those who have undergone resection, and in those receiving nutritional supplementation (in particular parenteral nutrition) or if the specific clinical scenario lends suspicion to a deficiency (such as poor wound healing).

2.4 Imaging after surgery (including ileo-anal pouch)

**Statement 2.4.1. ECCO-ESGAR Diagnostics GL (2018)**

Ileocolonoscopy is the reference standard in the diagnosis of post-operative recurrence after ileocolonic resection. Endoscopy is recommended within the first 6 to 12 months after surgery [EL3]

**Statement 2.4.2. ECCO-ESGAR Diagnostics GL (2018)**

FC, IUS, MR enterography, and SBCE can be considered as noninvasive alternatives to detect postoperative recurrence, in particular after small-bowel resection [EL2]

In the natural history of CD, intestinal resection is unavoidable in a significant proportion of patients. A majority of patients develop disease recurrence at or above the anastomosis and endoscopic recurrence precedes the development of clinical symptoms. Data from endoscopic follow up of patients after resection of ileocaecal disease have shown that in the absence of treatment, the post-operative endoscopic recurrence rate is approximately 65 to 90% within 12 months and 80 to 100% within 3 years of the operation [303, 304]. The rates of recurrence are also significant in patients after total proctocolectomy and permanent ileostomy. In a recent meta-analysis of 18 cohort studies, the risk of clinical recurrence was 28.0%, with a 5-year and 10-year median cumulative rate of 23.5% [305]. Identification and treatment of early mucosal recurrence may therefore prevent clinical recurrence.
Ileocolonoscopy is the reference standard in the diagnosis of post-operative recurrence by defining the presence and severity of morphologic recurrence. Data from endoscopic follow up of patients after resection of ileocaecal disease have shown that in the absence of treatment, the post-operative recurrence rate is approximately 65 to 90% within 12 months [303, 304]. Ileocolonoscopy is therefore recommended within the first year after surgery where treatment decisions may be affected. The Rutgeert’s score may be used for detailed description (see chapter 4 of this guideline).

Noninvasive modalities may also be accurate and efficient in detection of postoperative recurrence.

FC can accurately identify postoperative recurrence [306, 307]. In a meta-analysis of ten studies that evaluated the accuracy of FC for detection of endoscopic recurrence, the pooled sensitivity and specificity values for assessing suspected endoscopic recurrence were 0.82 and 0.61, respectively [308]. In a more recent prospective study, FC levels >100 μg/g indicated endoscopic recurrence (defined as Rutgeerts score ≥i2) with 89% sensitivity and 58% specificity and a NPV of 91%; the authors suggested that colonoscopy could have been avoided in 47% of patients. In an additional prospective study from the GETAID group, FC levels >100 μg/g were associated with a positive predictive value and NPV of 93% and 77%, respectively, for prediction of endoscopic recurrence [309].

Several imaging modalities are available to reliably diagnose postsurgical recurrence, including IUS, small-bowel follow through, CT enteroclysis or CT enterography including virtual colonoscopy, MR enteroclysis or MR enterography, SBCE, and white blood cell scintigraphy.

Several authors have previously emphasized the value of IUS in postoperative follow up and confirmed the observation of bowel wall thickening as an indicator for recurrence [310-312]. SICUS has shown an excellent correlation with the endoscopic Rutgeerts score (r=0.67; P=0.0001), reaching 87.5% accuracy for detecting CD recurrence [313]. SICUS is also considered to be superior to standard IUS in detecting postoperative CD recurrence after ileocaecal resection [314]. Bowel wall thickening was defined by thickness of >3.5 mm. SICUS prediction of recurrence was found to be correct in 100% of cases and confirmed by endoscopy [314]. In a recent retrospective series from Italy, the absolute incidence of new surgical intervention is 13% in patients with bowel thickness of 3 mm and 40% in patients with bowel thickness >6 mm [315].

CT enterography or CT enteroclysis are alternatives to endoscopy for assessing postoperative recurrence of CD activity [316]. In a prospective series that included 32 postoperative patients from China, a significant correlation between endoscopic and CT recurrence (r=0.782; P<0.0001) was demonstrated [317]. Due to false-negative findings, CT colonography has been tested for assessing the postoperative recurrence of CD with inconclusive results. However, CT colonography represents an alternative to conventional colonoscopy in noncompliant postsurgical patients with a rigid stenosis that does not allow passage of the endoscope [318]. However, due to concerns regarding cumulative radiation exposure, imaging modalities not associated with radiation (such as MR enterography or IUS) are preferable to CT enterography.
MR enterography may be an alternative to endoscopy as a diagnostic tool in postoperative recurrence evaluation in CD patients. Similar to the endoscopic Rutgeerts score for assessing postoperative recurrence, one study showed an objective evaluation using an MRI-based index of activity and severity for postoperative recurrence. This score achieved a high correlation with the endoscopic index, which allowed differentiation between mild and severe lesions [319] and prediction of the risk of clinical postoperative recurrence in CD patients [320].

Although the Rutgeerts score has been used to evaluate the efficacy of several drugs, there is a lack of information on whether mural healing changes seen by cross-sectional imaging techniques are in parallel to endoscopic MH.

Capsule endoscopy can also be used to access postoperative recurrence [321, 322]. A fair correlation between the modalities ($r^2=0.54–0.64; P<0.05$) was observed in a small pilot study that compared the Rutgeerts score calculated by capsule endoscopy and ileocolonoscopy [322]. An important advantage of capsule endoscopy is the ability to detect proximal small-bowel recurrence. However, data on the use of capsule endoscopy for this indication is currently very limited, and patency capsule evaluation should be recommended prior to capsule endoscopy to minimize the risk of retention.

In a recent meta-analysis, MR enterography, IUS, and SBCE had excellent accuracy (area under the curve $>0.9$ for all modalities) for detection of endoscopic recurrence as defined by a Rutgeerts score $\geq 2$ [323].

Statement 2.4.3. ECCO-ESGAR Diagnostics GL (2018)

Endoscopy with biopsies should be performed in the assessment of pouch-related symptoms [EL2]

The ileo-anal pouch is a well-established option for patients who require surgery for chronic UC. Despite excellent functional results, the short-term and long-term outcome of ileal pouch with anal anastomosis (IPAA) are determined by the occurrence of complications. These may be directly related to the surgery or may occur over the long term. Immediate postoperative complications include leakage, abscess formation, pelvic sepsis, and fistula formation. More chronic disorders following IPAA are pouchitis, cuffitis, irritable pouch syndrome, pouch stricture, pouch sinus, afferent loop syndrome, or small-bowel obstruction [324]. Following surgery, up to 40% of patients have a single episode of pouchitis (a nonspecific inflammatory condition at the ileal pouch reservoir) [325] within 12 months,
whereas 19% and 5% experience intermittent episodes and chronic pouchitis, respectively [326-328]. The incidence of pouch failure is up to 7% at 3 years and 9% at 5 years [329, 330].

Endoscopy plays a significant role in diagnosing and guiding therapy in patients with pouch complications [324, 331-334]. Importantly, the severity of symptoms does not always correlate with endoscopic or histological findings [335, 336]. Therefore, a cumulative clinical, endoscopic, and histological assessment is needed. Several diagnostic criteria are available and the most common in clinical use is the pouch disease activity index [337]. Furthermore, it is valuable to classify the phenotype of pouchitis before initiating therapy to provide guidance regarding treatment modalities and duration of treatment [338]. In case of antibiotic-refractory pouchitis, endoscopic evaluation can facilitate exclusion of contributory factors such as ischaemic pouchitis and infections [339]. Pouch endoscopy is essential in the diagnosis of CD of the pouch and prepouch ileitis [324, 334, 335].

FC levels are significantly elevated in cases of pouchitis. In a study that included 56 pouch patients, FC concentrations correlated closely with the objective pouchitis score, the pouch disease activity index, and endoscopic and histologic inflammatory scores (Spearman rank test, P-values <0.0001); FC levels ≥92.5 µg/g had a sensitivity of 90% and a specificity of 76.5% for detection of pouch inflammation [340]. Other potential biomarkers of pouch inflammation, such as faecal matrix metalloprotease-9 [341] and serum alpha-1 antitrypsin [342], are also being evaluated but are currently not in routine clinical practice.

Chapter 3 Detection of complications

3.1 Detection of strictures

Statement 3.1.1. ECCO-ESGAR Diagnostics GL (2018)

Cross-sectional imaging should be used to detect small-bowel strictures [EL2]. Due to radiation exposure with CT, the preferred methods are MRI and/or intestinal ultrasound (IUS). No imaging technique is currently able to determine the degree of fibrosis [EL3]

Despite wide heterogeneity in the definitions for strictures, the accuracy of intestinal ultrasound (IUS), CT enterography, and MR enterography is high for diagnosis of stenosis affecting the small bowel [81]. IUS is an accurate technique for detection of small-bowel stenosis. Based on pooled data using surgery as a reference standard, the sensitivity and specificity of IUS is 79% and 92%,
respectively [81]. Use of oral contrast agents, such as small intestine contrast ultrasound (SICUS), can improve the accuracy of IUS in detecting the presence and number of small-bowel stenosis; sensitivity increased from 74 to 89% in one study [131]. The sensitivity of CT enterography for stenosis detection was 92% and specificity was 100% when CT was compared with ileocolonoscopy [343] [344, 345]. Studies using endoscopy and surgery as a reference standard reported a sensitivity of 85% and 90%, respectively, with a specificity of 100% [82, 346]. MRI studies with an adequate reference standard (endoscopy, surgery, or both) for diagnosis of stenosis showed a sensitivity of 89% and a specificity of 94% [81]. The accuracy had a tendency to improve using enterolysis (i.e. enteric contrast introduced via nasojejunal intubation rather than oral) as compared to enterography (sensitivity of 100% versus 86% and specificity of 100% versus 93%, respectively) [253]. Direct comparison of CT and MRI for diagnosis of stenosis indicated a similar sensitivity (85% versus 92%) and specificity (100% versus 90%) [82]. The use of luminal contrast and anti-peristaltic agents is recommended for CT enterography and MR enterography [347].

Strictures in Crohn’s disease (CD) are transmural and contain variable proportions of inflammatory and fibrotic tissue [348]. Quantification of active inflammation versus fibrosis is challenging. With regards to current techniques used in clinical practice, no technique is sufficiently accurate to assess the degree of fibrosis in a stricture with adequate precision to guide clinical decisions. While the stratified echo pattern of the different layers of the intestinal wall components of a stricture has been associated with collagen deposition, this approach lacks consistency [349]. On CT enterography, the presence of fibrosis was linked to stenotic lesions, but could not distinguish inflammation from fibrosis [350]. Conventional-sequence MR enterography revealed conflicting results for fibrosis characterization [351, 352]. Rimola et al. developed a technique using gadolinium enhancement between 70 seconds and 7 minutes on MR enterography. This approach was able to distinguish mild or moderate fibrosis from severe fibrosis irrespective of the degree of inflammation [353]. This approach awaits external validation.

Although several novel imaging techniques have been proposed, data are limited, acquisition methods are unstandardized, and there is limited evidence to support external validity. These techniques include MR with dynamic contrast-enhanced technique [354], magnetization-transfer MR [355, 356], ultrasound elastography [357, 358], or contrast-enhanced ultrasound (CEUS) [359, 360]. While stenosis can be detected by endoscopy, most investigators use the ability to pass the endoscope as a measure of stenosis. The proportion of fibrosis cannot be evaluated precisely by biomarkers, endoscopy, or histology. There is no consistent approach regarding strategy for monitoring strictures over time and with which method.

While not the preferred technique, ileocolonoscopy can be used for stricture diagnosis. The commonly used definition is a narrowing that cannot be passed with an endoscope [361]. An ileocolonoscopy is not necessary in all cases after a stricture has been detected on cross-sectional imaging, but should be considered if endoscopic therapy through endoscopic balloon dilatation is a valid therapeutic approach [362] and in case of colonic strictures when malignancy cannot be excluded.
Consistent with the observation that patients with ulcerative colitis (UC) and patients with colonic CD are at an increased risk of developing colorectal cancer (CRC) [363-365], detection of a new colonic stricture should lead to a careful diagnostic workup to exclude malignancy. A recently published population-based study suggested that colonic strictures at diagnosis or during follow up are associated with a 3.6% and 4.9% probability of CRC at 5 and 10 years, respectively [366]. According to the ECCO evidence-based consensus for endoscopy in IBD, patients with strictures detected within 5 years should be considered 'high risk' and receive surveillance colonoscopy yearly. Malignancy is more frequent in the CD-affected colon and the incidence is comparable to UC [367, 368]. In a GETAID study, dysplasia or cancer was detected in 3.5% of patients with IBD who underwent surgery for colonic strictures [369]. In addition, small-bowel adenocarcinoma is rare but can be fatal if overlooked [370]. The endoscopist should therefore have a low threshold for taking a biopsy before endoscopic balloon dilatation [370]. In addition, the use of paediatric endoscopes with a smaller diameter may permit stricture traversal. Cross-sectional imaging should be considered as a complementary diagnostic modality. Currently, there is no method (including histology) that can definitively rule out malignancy in a patient with IBD and colonic strictures.

3.2 Detection of fistulae and abscesses

3.2.1 Detection of intra-abdominal fistulae and abscesses

In a systematic review for the diagnosis of intra-abdominal fistulizing lesions, cross-sectional imaging showed the following accuracy: for CT with surgery and endoscopy as reference standard, the sensitivity was 70% and specificity 97%; MRI with surgery or endoscopy as the reference standard showed a sensitivity of 76% and specificity of 96% for fistulae diagnosis; IUS with surgery, barium studies, and colonoscopy as the reference standard showed a sensitivity of 74% and specificity of 95% [81]. Oral contrast agents do not improve accuracy of IUS for detection of internal fistulae [131]. If available, CT or MRI are preferable for detection of intra-abdominal or pelvic fistulae over ultrasound; MRI has the advantage of no radiation exposure [80, 81]. Cross-sectional imaging has a pivotal role in the assessment of penetrating complications of CD. In one study, there was no clinical
fistula or abscess suspicion from pre-CT examination in half of patients with penetrating CD complications. Cross-sectional imaging changed management in more than three quarters of these patients [371]. White blood cell scintigraphy is not indicated for diagnosis and characterization of fistulae.

A systematic review revealed the following point estimates for diagnosis of abscesses: using surgery as a reference standard, IUS had a sensitivity of 84% and a specificity of 93%, which was dependent on disease location in CD [81]. Detection of intra-abdominal abscesses via CT with surgery as the reference standard revealed a sensitivity of 86% and a specificity of 88% [350]. One prospective study showed a sensitivity of 85% and specificity of 95% of CT for intra-abdominal abscesses [372]. CT and ultrasound showed an overall high and comparable accuracy in the detection of intra-abdominal abscesses, although CT showed a slightly greater positive predictive value than ultrasound. CEUS has been shown to differentiate between an intra-abdominal phlegmon and abscess with high accuracy [373]. The accuracy of MRI for abscess detection using surgery as the reference standard showed sensitivities ranging from 86 to 100% and specificities from 93 to 100% [352, 374, 375]. A systematic review of these three studies showed a sensitivity of 86% and a specificity of 93% for MRI detection of abscesses [81]. Endoscopy is not used for evaluation of internal penetrating disease due to an inability to image extramural structures.

3.2.2 Detection of perianal fistulae and abscesses

Statement 3.2.2.1. ECCO-ESGAR Diagnostics GL (2018)

MRI is the most accurate imaging modality for diagnosis and classification of perianal CD and is the recommended first-line test [EL1]. Transrectal ultrasonography (TRUS) is superior to clinical examination and is an alternative to MRI [EL2]. Combining any modality of MRI, examination under anaesthesia (EUA), or TRUS improves accuracy [EL2]

Statement 3.2.2.2. ECCO-ESGAR Diagnostics GL (2018)

EUA with drainage is recommended if a perianal abscess is suspected and should not be postponed if pelvic imaging is not immediately available [EL2]

Statement 3.2.2.3. ECCO-ESGAR Diagnostics GL (2018)

Endoscopic evaluation of the rectum is essential to determine the most appropriate management strategy for perianal CD [EL2]
Three diagnostic tests are commonly used alone or in combination for the diagnosis and classification of perianal disease, namely examination under anaesthesia (EUA), MRI, or transrectal ultrasonography (TRUS). Both TRUS (with and without hydrogen peroxide) and MRI can identify and classify fistulous tracts with a diagnostic accuracy for MRI ranging from 80 to 100% in most reported studies. The diagnostic accuracy of TRUS is more variable and ranges from 50 to 100% [165, 170, 376-385]. MRI is the recommended first-line test, as TRUS is hindered by patient discomfort, cannot be performed in the presence of stenosis, and has a smaller field of view. EUA by an experienced surgeon has long been considered the reference standard for assessment of perianal CD. However, a prospective blinded study comparing EUA, MRI, and TRUS found diagnostic accuracies of 91%, 87%, and 91%, respectively, with 100% accuracy when any two of the tests were combined [169]. A larger prospective clinical trial compared preoperative digital rectal examination (33% sensitivity), TRUS (75% sensitivity), and body-coil MRI (85% sensitivity). MRI may change management in patients with perianal CD by detecting an abscess not suspected clinically [376, 386] and should therefore precede EUA unless there is a need for immediate drainage of sepsis. Although the use of EUA may be limited by luminal stenosis, dilatations during the procedure can be performed.

Undiagnosed fistula extensions and abscesses are major causes of recurrent disease after attempted surgical cure [377]. Furthermore, full knowledge of the presence and extent of these secondary tracts is required for appropriate medical therapy, particularly with anti-TNF agents [166]. Accurate classification of perianal fistulae is thus essential prior to starting therapy. Two prospective studies evaluated the effect of preoperative MRI on clinical outcome after surgical treatment for perianal fistulizing disease [376, 377]. Both studies showed that MRI revealed additional and clinically relevant information to the surgeon performing EUA. A prospective comparison of modalities using a robust outcome-based reference standard found MRI superior to TRUS for fistula classification and detecting abscesses [170]. In general, MRI is preferred in CD, especially in recurrent or suspected complex disease.

Endoscopy can facilitate detection of perianal disease and has a role in assessing the degree of inflammation in the rectum, which may affect management [105]. Endoscopy has not been shown to be useful in monitoring perianal disease or assessing response to fistula therapy.

Transperineal ultrasound (TPUS) has been evaluated in small studies for the documentation of perianal disease and may have clinical utility [387, 388].

3.3 Detection of pouch complications

| Statement 3.3.1. ECCO-ESGAR Diagnostics GL (2018) | 41 |

Downloaded from https://academic.oup.com/ecco-jcc/advance-article-abstract/doi/10.1093/ecco-jcc/jjy113/5078195 by University College London user on 28 August 2018
Inflammatory and non-inflammatory complications of the ileal pouch anal anastomosis (IPAA) are common and include strictures, abscesses, fistulae, and sinus tracts culminating in pouch failure in up to 9% of cases at 5 years [329, 330, 332, 389]. These complications can be immediate postoperative or long-term. In the case of IPAA stenosis, fistulae, abscesses, and sinuses, EUA by an experienced IBD surgeon is important for diagnosis and timely treatment of most pathologies. The choice of diagnostic modality depends on the clinically suspected disorder, local expertise, and availability. Endoscopy is essential to obtain information on mucosal status and for diagnosis of intraluminal or anastomotic complications, such as strictures. Endoscopic balloon dilatation can be used to treat pouch stricture [390, 391]. For suspected extraluminal complications, such as abscesses, fistulae, or sinus tracts [392, 393], pelvic CT, MRI, and TRUS or TPUS are sensitive methods that allow the identification and characterization of septic problems [170]; use of these modalities depends on local availability and experience level. Unfortunately, the proportion of fibrosis versus inflammation cannot be assessed precisely by any currently available diagnostic tool [394-396]. Contrast pouchography can assist in assessment of pouch strictures, pouch fistulae, and leakage [100] but is only used in limited number of centres. A correlation of pelvic CT, MRI, pouch endoscopy, and retrograde pouchography findings with clinical outcome revealed a reasonable accuracy for diagnosis of strictures, fistulae, sinuses, and pouch leaks with all methods [397]. CT had the lowest accuracy for small-bowel strictures (74%); MRI had the lowest accuracy for pouch sinuses (68%). A combination of two imaging tests increased diagnostic accuracy to 100%. In the acute post-operative setting, complications of IPAA include anastomotic leaks and abscesses. Leaks from the tip of the J-pouch and the pouch-anal anastomosis often result in pelvic abscesses. Detection of anastomotic dehiscence after IPAA is possible using transanal ultrasound and TPUS, although pelvic CT or MRI scanning is usually required to outline the full extent of the complication and guide drainage [396, 398]. Complications of the pouch should be discussed in a multidisciplinary team setting to individualize management.

3.4 Detection of emergency complications

Statement 3.4.1. ECCO-ESGAR Diagnostics GL (2018)
In acute severe colitis a plain abdominal radiograph is an acceptable first study to detect toxic megacolon. In selected cases, CT could be indicated as an initial method to screen for complications [EL3].

Diagnosis of toxic megacolon is usually made by clinical signs of systemic toxicity supported by imaging confirmation. Detection of transverse colonic dilatation >5.5 cm by means of plain abdominal X-ray is still the most established radiological definition of toxic megacolon [399]. Some case series have shown that in patients with toxic megacolon, CT scan and IUS can be promising alternatives that provide additional information [400, 401]. A CT scan is an important tool for diagnosis of associated perforation or ascending pylephlebitis. A study observed that among 18 patients with toxic megacolon (4 with underlying UC), CT scans revealed abdominal complications in four patients missed clinically and on plain abdominal films [400]. Larger clinical studies are warranted to assess the diagnostic benefit of cross-sectional radiological studies in the assessment of toxic megacolon.

Statement 3.4.2. ECCO-ESGAR Diagnostics GL (2018)

When a perforation is suspected, CT should be performed in all patients with acute abdominal pain and established diagnosis of IBD [EL2].

Spontaneous free perforation is a rare but serious event in CD but can be more common in acute severe colitis. Spontaneous free perforation may result from severe inflammation or superimposed malignancy. It is estimated that approximately 1 to 2% of patients with CD will present with a free perforation initially or sometime over their disease course [402, 403].

In IBD patients, intestinal perforation frequently presents as a peri-intestinal abscess that may be detected by cross-sectional imaging methods such as IUS, MRI, or CT. A systematic review showed that in this context the three techniques have a high accuracy for identification of fistulae, abscesses, and stenoses (sensitivities and specificities of 0.80), although IUS yields more false-positive results for abscesses [81].

3.5 Detection of postoperative complications
Statement 3.5.1. ECCO-ESGAR Diagnostics GL (2018)

Acute postoperative complications in IBD patients (mainly anastomotic leaks and abscesses) should be initially investigated by CT [EL3]. Ultrasound may be an alternative first-line investigation, but should be followed by immediate CT, if negative or equivocal. [EL4]

Anastomotic leaks after intestinal surgery may be promptly diagnosed clinically due to specific clinical presentation in the postoperative period. However, when anastomotic leaks are suspected in cases of atypical clinical manifestations, correct and rapid radiological diagnosis is necessary for successful management. Few studies have been designed to assess detection of these complications in CD [81] and most are derived from the surgical literature [404-406]. A prospective database populated over a 10-year period showed that anastomotic leaks are frequently diagnosed late in the postoperative period and often after initial hospital discharge (median time 12.7 days, range 1–38) [404]. In this study, CT was the preferred imaging modality [404]. In contrast, other studies showed that most postoperative CT features overlap between patients with or without clinically important anastomotic leaks and that CT studies performed on patients shortly after abdominal surgery are not definitive. A negative CT does not exclude postoperative lower gastrointestinal tract leaks [405, 406]. A combination of CT, laboratory examinations, and clinical signs and symptoms will optimize diagnosis of such complications.

There is no evidence that the addition of intraluminal contrast is more sensitive for detection of anastomotic dehiscence in IBD, as peri-anastomotic located fluid-containing gas is the most prevalent sign of anastomotic insufficiency [406]. Selected use of intraluminal contrast can be individualized according to physician preference.

3.6 Surveillance for colorectal cancer in IBD patients with colonic inflammation

(ECCO statement 8D [adapted from statement 13D in Annese et al.13])

Screening colonoscopy should be offered 8 years after onset of symptoms to all patients to reassess disease extent and exclude dysplasia [ELS]
Statement 3.6.2. ECCO-ESGAR Diagnostics GL (2018)

(ECCO statement 8E)

When disease activity is limited to the rectum without evidence of previous or current endoscopic or microscopic inflammation (or both) proximal to the rectum, inclusion in a regular surveillance colonoscopy program is not necessary [EL2]

Statement 3.6.3. ECCO-ESGAR Diagnostics GL (2018)

(ECCO statement 8F)

In patients with concurrent primary sclerosing cholangitis (PSC), annual surveillance colonoscopy should be performed following the diagnosis of PSC, irrespective of disease activity, extent, and duration [EL3]

Statement 3.6.4. ECCO-ESGAR Diagnostics GL (2018)

(ECCO statement 8G [adapted from statement 13E in Annese et al.13])

Ongoing surveillance should be performed in all patients apart from those with proctitis [EL3]. Patients with high-risk features (e.g. stricture or dysplasia detected within the past 5 years, PSC, extensive colitis with severe active inflammation) should have their next surveillance colonoscopy scheduled for 1 year [EL4]. Patients with intermediate risk factors should have their next surveillance scheduled for 2 to 3 years. Intermediate risk factors include extensive colitis with mild or moderate active inflammation, post-inflammatory polyps, or a family history of colorectal cancer (CRC) in a first-degree relative diagnosed at age 50 years and above [EL5]. Patients with neither intermediate nor high-risk features should have their next surveillance colonoscopy scheduled for 5 years [EL5]

Statement 3.6.5. ECCO-ESGAR Diagnostics GL (2018)

Colonoscopic surveillance is best performed when ulcerative colitis (UC) is in remission, because it is otherwise difficult to discriminate between dysplasia and inflammation on mucosal biopsies [EL5]

Surveillance colonoscopy should take into account local expertise. Chromoendoscopy with targeted biopsies has been shown to increase dysplasia detection rate [EL2]. White-light endoscopy is less accurate. If white-light endoscopy is used, random biopsies (quadrant biopsies...
every 10 cm) and targeted biopsies of any visible lesion should be performed [EL3]. High-definition endoscopy should be used if available [EL2]

Statement 3.6.7. ECCO-ESGAR Diagnostics GL (2018)

Where dysplasia of any grade is found without an associated endoscopically visible lesion, urgent repeat chromoendoscopy should be performed by an experienced endoscopist to determine whether a well-circumscribed lesion exists and to assess for synchronous dysplasia [EL5].

A patient with confirmed low-grade dysplasia detected in mucosa without an associated endoscopically visible lesion should undergo repeat chromoendoscopic colonoscopy with additional random biopsies within 3 months [EL5]

(ECCO statement 8K)

Presence of low-grade or high-grade dysplasia should be confirmed by an independent gastrointestinal specialist pathologist [EL5]

Longstanding UC and CD with colonic inflammation are associated with an increased risk of CRC with a variable estimate between studies [363, 364] [365]. However, the risk of CRC seems to decline over time [407-409]. Possible reasons are the emergence of effective surveillance strategies, better control of inflammation with drugs, and a modified approach to maintenance therapy or colectomy, as stated in previous guidelines [410].

On the basis of systematic endoscopic assessment, together with medical and family history of the patient, surveillance colonoscopy programs have been developed to reduce CRC-associated morbidity and mortality [363]. At the onset of these programs, an initial screening colonoscopy is performed to reassess disease extent and confirm the absence of dysplastic lesions [363]. The timing of surveillance colonoscopies should be based on the level of risk of the patient, as extensively discussed in the recent ECCO consensus [363] (Table x). The suggested timeline for surveillance in Crohn’s colitis, though scientific data is more limited, should be applied as for UC.

**CRC, colorectal cancer; PSC, primary sclerosing cholangitis; OLT, orthoptic liver transplantation**

Good bowel preparation is essential for an efficient surveillance colonoscopy, since the quality of the preparation in UC patients significantly affects the lesion detection rate [411].

A recent colitis surveillance study demonstrated that high-definition colonoscopy improves dysplasia detection in comparison to standard definition [363, 412]. Targeted biopsies have been shown to be noninferior to random biopsies for neoplasia detection rate per colonoscopy in a randomized controlled trial [363, 413]. Spraying dyes, such as methylene blue or indigo carmine [414-416], highlight subtle changes in the colonic mucosa architecture and can improve the detection rate of dysplasia [417]. There is abundant evidence from clinical trials and real-life studies that chromoendoscopy is superior to white-light endoscopy for dysplasia detection [418-420] [421] [422-426], independent of operator familiarity or from the availability of high-resolution endoscopy. Narrow-band imaging and endomicroscopy cannot currently be recommended for dysplasia screening in IBD [363].

### 3.7 Diagnostic and monitoring techniques during pregnancy

**Statement 3.7.1. ECCO-ESGAR Diagnostics GL (2018)**
**IUS and abdominal MRI without intravenous gadolinium are the safest techniques to examine pregnant women in whom IBD is known or suspected, regardless of the trimester [EL5]**

<table>
<thead>
<tr>
<th>Statement 3.7.2. ECCO-ESGAR Diagnostics GL (2018)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Endoscopy is generally considered to be safe in pregnancy; however, procedures should only be performed when there is a strong indication and clear clinical benefit [EL3]</td>
</tr>
</tbody>
</table>

Data are scarce concerning the medical imaging of pregnant women in whom IBD is known or suspected. Recent guidelines by the American College of Obstetricians and Gynecologists state that ultrasound, MRI, CT, and nuclear medicine imaging techniques are theoretically safe if used prudently [427]. The main concerns regarding these techniques are increased foetal temperature caused by application of high-frequency ultrasound or a magnetic field and foetal radiation exposure, either via X-ray or radioisotopes.

Ultrasound and MRI are the best choice for pregnant women, but application of either can theoretically increase the temperature of maternal and foetal tissues [428, 429]. The Food and Drug Administration limits the spatial-peak temporal average intensity of ultrasound transducers to 720 mW/cm² [427]. Ultrasound examination should be performed according to the ‘As Low As Reasonably Achievable’ principle [430], accounting for exposure time related to the thermal index generated during the procedure (keeping this value <1) [431] [432]. No specific data apply to IBD populations.

Regarding MRI, a recent retrospective survey of 1,424,105 deliveries from the province of Ontario compared those with first-trimester MRI (n=1737) to no MRI (n=1,418,451). MRI did not confer additional risk of congenital anomalies, neoplasms, or vision or hearing loss. No additional risk of nephrogenic systemic fibrosis was found when gadolinium-enhanced MRI (n=397) was compared with no MRI (n=1,418,451). Gadolinium-enhanced MRI at any time during pregnancy was associated with an increased risk of a broad set of rheumatologic, inflammatory, or infiltrative skin conditions (adjusted hazard ratio 1.36; 95% CI 1.09–1.69) and for stillbirth or neonatal death (adjusted relative risk 3.70; 95% CI 1.55–0.85) [433]. Another retrospective study of 751 neonates exposed to 1.5T MRI in utero compared with 10,042 unexposed neonates found no difference between groups regarding birth weight or incidence of hearing impairment or deafness [434].

Specific data on MRI in pregnant women with IBD are limited. Stern et al. reported nine pregnant women (7 with established CD) who underwent unenhanced MRI. Features typical of active CD were identified with their protocol (mural thickening ≥3 mm, ulcers, mural oedema, ‘comb sign’, phlegmon, abscesses, and fistulae). MRI detected complications in four women and was sufficiently
accurate to inform medical management [435]. One case report described MR colonography used safely to examine a pregnant woman of 20 weeks gestational age with acute severe colitis, indicating conservative therapy that avoided colectomy [436]. Another case report described a pregnant woman of 26 weeks gestational age who underwent unenhanced MRI to diagnose adhesions following ileo-anal pouch, with no adverse events [437]. Another case report did not reveal any safety concerns in a pregnant woman with fistulizing CD [438].

X-ray exposure is associated with an increased risk of congenital malformation [439, 440] and childhood cancer [441], estimated at 6% per Gy [440]. However, exposure at ≤50 mGy is considered safe at any trimester [440]. In the absence of data for IBD patients, Hurwitz et al. showed that multidetector row CT to investigate suspected appendicitis conferred a dose of 1.52 to 1.68 cGy and 2 to 4 cGy at months 0 and 3, respectively [442]. Unless potential risks are outweighed by clinical need, current data do not support the use of CT or any other X-ray technique. Due to the absence of specific data regarding use of radioisotopes in pregnant women with suspected or diagnosed IBD, radioisotopes should be avoided in this patient population.

Limited evidence exists regarding the utility and safety of endoscopy in pregnant women with IBD. Due to potential complications described in the recent ECCO pregnancy and reproduction consensus [443], endoscopy in pregnancy should be reserved for strong indications. To avoid vena cava compression, pregnant patients should be placed in the left pelvic tilt or left lateral position before, during, and after the endoscopic procedure. Close attention should be paid to appropriate drug selection, using drugs appropriate for pregnancy and using the minimum dose possible to achieve the desired effect. Sedative drugs should be administered to provide patient comfort; over-sedation should be avoided.

### 3.8. Diagnostics for biliary extra-intestinal manifestations of IBD

**Statement 3.8.1. ECCO-ESGAR Diagnostics GL (2018)**

Ultrasound is the first-line noninvasive imaging procedure in the workup of elevated liver enzymes, cholestasis, or both [EL1]. Magnetic resonance cholangiopancreatography should be considered if ultrasound and serology are inconclusive [EL1]

**Statement 3.8.2. ECCO-ESGAR Diagnostics GL (2018)**

(ECCO EIM Guidelines: statement 7B in M. Habord et al.16)

If high-quality magnetic resonance cholangiography is normal in a patient with IBD and suspected PSC, an ultrasound-guided liver biopsy should be considered to diagnose small-duct PSC [EL2]
Statement 3.8.3. ECCO-ESGAR Diagnostics GL (2018)

(ECCO EIM Guidelines: statement 7H in M. Habord et al.16)

There is no evidence-based follow up regimen proven to detect biliary neoplasia earlier in PSC. Annual ultrasonography to detect gallbladder mass lesions is recommended [EL4]. Additional imaging (MRI/MRC, CT, or endoscopic retrograde cholangiography [ERC]) should be performed without delay if cholangiocarcinoma is suspected [EL1]

(ECCO EIM Guidelines: statement 7E in M. Habord et al.16)

In PSC patients with clinical or radiological suspicion of significant strictures or cholangiocarcinoma, ERC is recommended to diagnose strictures that may be amenable to endoscopic dilatation (with or without stenting) and for brush cytology specimen evaluation [EL2]. Prophylactic antibiotic therapy is recommended [EL1]

The statements above have been included in this ECCO diagnostic guideline for completion of endoscopic or cross-sectional imaging diagnostics of extra-intestinal biliary involvement in patients with IBD. For detailed explanation and references please refer to the ECCO EIM guideline.
CONFLICT OF INTEREST STATEMENT:

ECCO and ESGAR have diligently maintained a disclosure policy of potential conflicts of interests (CoI). The conflict of interest declaration is based on a form used by the International Committee of Medical Journal Editors (ICMJE). The CoI statement is not only stored at the ECCO Office and the editorial office of JCC but also open to public scrutiny on the ECCO website (https://www.ecco-ibd.eu/about-ecco/ecco-disclosures.html) providing a comprehensive overview of potential conflicts of interest of authors.

DISCLAIMER TEXT:

The ECCO-ESGAR Consensus Guidelines are based on an international Consensus process.

Any treatment decisions are a matter for the individual clinician and should not be based exclusively on the content of the ECCO-ESGAR Consensus Guidelines.

The European Crohn’s and Colitis Organisation, the European Society of Gastrointestinal and Abdominal Radiology and/or any of its staff members and/or any consensus contributor may not be held liable for any information published in good faith in the ECCO-ESGAR Consensus Guidelines.
