Frailty is a state characterized by increased vulnerability to stressors due to loss of physiological reserve across multiple systems, and associated with various negative health outcomes.<sup>4</sup> Since some of these negative outcomes can directly and indirectly predispose frail individuals to ED visits, frailty may be a risk factor for ED utilization, however, there is only limited evidence in the literature regarding the associations. The objectives of the present study were to perform a systematic review and meta-analysis on frailty as a predictor of ED utilization among community-dwelling older adults.

#### METHOD

Five electronic databases (EMBASE, Medline, CINAHL, PsycINFO, and AMED) were systematically searched in September 2018 for prospective cohort studies published in 2000 or later examining risk of ED visits according to frailty status categories (frail, prefrail, and robust) defined by validated frailty criteria among community-dwelling older adults with a mean age of  $\geq$ 60. A protocol developed according to the PRISMA statement and search strategy were registered at PROSPERO (CRD42018104640). If the same cohort was used by multiple studies, the results with the largest number of participants were chosen. Studies were examined for risk of bias and methodological quality using the Newcastle-Ottawa scale and considered to have low risk of bias and adequate methodological quality if they meet  $\geq$ 5 of 9 items. Odds ratios (ORs) of ED visit risk according to frailty were combined by meta-analysis. Publication bias was assessed by visually inspecting a funnel plot. All data analyses were conducted using Review Manager 5 (The Cochrane Collaboration, Copenhagen, Denmark).

#### RESULTS

Among 1,467 citations identified, four studies<sup>5-8</sup> (a total of 2,112 participants, mean followup 1.4 years) were included. All four studies were considered to have adequate methodological quality and therefore low risk of bias. There is no apparent asymmetry in the funnel plot, suggesting no evidence of publication bias. A fixed-effect meta-analysis was used based on low heterogeneity (I<sup>2</sup>=25% for frail, I<sup>2</sup>=0% for prefrail) and showed that both frailty and prefrailty were significant predictors of ED visit (frailty: 4 studies, pooled OR=2.14, 95%CI=1.58-2.91, p<0.001, prefrailty: 4 studies, pooled OR=1.46, 95%CI=1.17-1.82, p<0.001). There was a dose-response relationship between the degree of frailty and ED visit risk (p for subgroup differences=0.05). (**Figure**)

#### DISCUSSION

The present review identified four studies examining ED utilization risk according to frailty and the meta-analysis showed that older adults with frailty and prefrailty were more likely to use the ED than the robust in a dose-response manner.

One study used the Frailty Index to measure frailty and examined risk of ED utilization over two years in 1679 Dutch community-dwelling older adults.<sup>9</sup> Rates of ED or out-of-hour GP surgery visits increased as the Frailty Index increased over tertile groups: 11.7% (least frail), 24.4%, and 42.9% (most frail).<sup>9</sup> In another study, researchers involved in the INTER-FRAIL

study developed a postal questionnaire for frailty screening by mail, and showed that ED visit risk was 70% higher among those defined as frail compared with the non-frail (hazard ratio=1.67, 95%CI=1.53-1.84), using a competing risk regression model.<sup>10</sup>

The strength of the present study include comprehensive methodology with an extensive and reproducible search strategy using five databases and assessments of methodological quality, heterogeneity, and publication bias. However, the present study is not without limitations. Firstly, only a small number of studies were found; therefore, sensitivity, subgroup, and meta-regression analyses were not possible. Secondly, there is a possibility that other relevant studies may have been missed, especially since the entire systematic review process was conducted by one investigator. Thirdly, although it is preferable to use adjusted effect measures for a meta-analysis, unadjusted ORs were calculated and used for the meta-analysis for one study.<sup>5</sup>

## **Conclusion/Relevance**

The present review highlights the first pooled evidence that frailty is a significant predictor of ED utilization among community-dwelling older adults. Given frailty is not irreversible,<sup>4</sup> effective frailty interventions may reduce ED utilization of older adults and its related consequences, such as emotional stress due to unfamiliar environment and disrupted daily life, potential hospitalization, iatrogenic adverse outcomes, and healthcare burden.
