Individualized outcome prediction after postoperative AED withdrawal in children – manuscript, figures & tables

Abstract

The objective of this study was to create a clinically useful tool for individualized prediction of seizure outcomes following antiepileptic drug withdrawal after pediatric epilepsy surgery. We used data from the European retrospective *TimeToStop* study, which included 766 children from 15 centers, to perform a proportional hazard regression analysis. The two outcome measures were seizure recurrence and seizure-freedom in the last year of follow-up. Prognostic factors were identified through systematic review of the literature. The strongest predictors for each outcome were selected through backward selection, after which nomograms were created. The final models included three to five factors per model. Discrimination in terms of adjusted concordance-statistic was 0.68 (95% confidence interval [CI] 0.68-0.69) for predicting seizure recurrence and 0.73 (95%CI 0.72-0.75) for predicting eventual seizure-freedom. An online prediction tool is provided on www.epilepsypredictiontools.info/tswithdrawal [*currently only available for review process*]. The presented models can improve counseling of patients and parents regarding postoperative AED policies, by estimating individualized risks of seizure recurrence and eventual outcome.

Individualized outcome prediction after postoperative AED withdrawal in children – manuscript, figures & tables

Introduction

After successful pediatric epilepsy surgery a pressing question for many patients and their caretakers is whether and when to reduce antiepileptic drugs (AEDs). Being able to discontinue drugs is the ultimate proof of successful epilepsy surgery. Stopping medication will prevent further drug adverse effects and may improve cognitive domains, such as psychomotor speed, executive functions and IQ¹⁻⁴. The decision to withdraw AEDs is partially based on an assessment of the risk of seizure recurrence. Predictors of seizure recurrence on a group level have been identified in previous publications⁵⁻¹⁰, but prediction of relapse is not yet possible for an individual patient.

The *TimeToStop* study previously showed that early withdrawal unmasks surgical failure but is not related to long-term seizure outcomes⁶. This conclusion was based on multivariable survival analysis, but did not yet enable individualized prediction of AED withdrawal outcomes. We now use the *TimeToStop* data to create nomograms and a web-based tool to enable estimation of individual risks, analogous to the recently developed prediction models for non-surgical patients¹¹.

Individualized outcome prediction after postoperative AED withdrawal in children – manuscript, figures & tables

Methods

Data of 766 patients were available from the *TimeToStop* study; for an extensive description of data collection and definitions we refer to the earlier report⁶. In short, patients were retrospectively identified within 15 pediatric epilepsy surgery centers in Europe. Patients were included if they had epilepsy surgery between 2000 and 2008, were younger than 18 years at surgery, had at least 1 year of follow-up after surgery and if postoperative AED withdrawal was initiated. Data were collected on clinical, surgical and seizure outcome parameters.

Two outcome measures were used: first, seizure recurrence after start of AED withdrawal and second, the seizure status at final follow-up with favorable outcome being defined as seizure-freedom (including freedom from auras) for at least one year at final follow-up. We decided not to model for 'cure' (seizure- and AED freedom at final follow-up), which was the third outcome measure in the original *TimeToStop* study, because the decision to completely discontinue medication is dependent on the policy of the individual physician, and these policies may change over time or may already have changed. A systematic review on risk factors of postoperative AED withdrawal previously identified 12 potential factors predictive of outcome¹², listed in supplementary Table 1. These factors were all available in the *TimeToStop* dataset.

Missing data were analyzed and imputed through multiple imputations using predictive mean matching. Heterogeneity between centers was tested, and when present, random-effects modeling was used. Assumptions were tested for continuous variables; if the linearity assumption was violated restricted cubic splines with three knots were used. Proportional

1 Individualized outcome prediction after postoperative AED withdrawal in children – manuscript, figures & tables

2
3 hazard (Cox) regression analysis was used to account for different follow-up duration. For
4
5 seizure recurrence, censoring time was the time to seizure recurrence. For seizure-freedom,
6
7 censoring time was time to seizure recurrence, only for those with unfavorable outcome. All
8
9 patients with favorable outcome were censored at maximum follow-up. To create a useful set
10
11 of predictors, the Akaike Information Criterion was used for backward selection of strongest
12
13 predictors.
14
15
16
17

18
19 For the purpose of the prognostic models, variables with three or four items of which only one
20
21 was significantly different from the reference category were dichotomized, so that the non-
22
23 significant categories were collapsed with the reference category. This was done for magnetic
24
25 resonance imaging (MRI; multifocal MRI abnormalities versus focal MRI abnormality and
26
27 normal MRI), for pre-withdrawal electroencephalography (EEG; interictal epileptiform
28
29 discharges versus no such discharges or no EEG performed) and for completeness of resection
30
31 (incomplete resection of the anatomical lesion versus complete resection or completeness not
32
33 determined). Within the nomograms, risk calculation of seizure recurrence was enabled for two
34
35 and five years after start of AED withdrawal, and calculation of eventual seizure-freedom was
36
37 set at six years. We chose six years after start of AED withdrawal to model the chance of
38
39 eventual “long-term” seizure freedom, creating an one-year longer interval than the latest
40
41 calculated 5-years relapse risk, as this intuitively allows for an extra period of time to regain
42
43 seizure-freedom after restart of medication should a late recurrence have occurred.

Individualized outcome prediction after postoperative AED withdrawal in children – manuscript, figures & tables

Results

One percent of data were missing and imputed (suppl. Table 2). The seizure outcomes after AED withdrawal were: seizure recurrence in 95/766 patients (12%), seizure-freedom in the last year of follow-up in 733/760 patients (96%). Median follow-up after start of AED withdrawal was 39 months (interquartile range 21-67 months) (suppl. Table 3). Univariable relations between potential predictors and outcomes are shown in supplementary Table 4.

One of the parameters, the presence of postoperative seizures (excluding seizures in the first two postoperative weeks), was not included in the analysis because none of the 13 cases experienced seizure recurrence and consequently no parameters could be estimated. The median time to reduction for these patients was 24 months (IQR 19-37), compared to 13 months (IQR 6-24) in the patients without postoperative seizures. AED status at final follow-up was known for 11 of these: six patients successfully discontinued AEDs, five were still using AEDs.

The strongest predictors were selected through backward selection, resulting in two models. Table 1 shows the outcome of multivariable Cox regression of these models. Figure 1 is the visualization of the models in the form of nomograms. The predictors for each model and model parameters are listed below. Heterogeneity between centers was low and a regular (fixed-effects) Cox regression was performed. The nomograms were converted to a web-based tool, accessible at <URL> [*sub site not yet accessible for wider public but for the review process accessible at www.EpilepsyPredictionTools.info/ttswithdrawal/*]. Calibration of the models is visualized in Figures 1 C and D.

1 Individualized outcome prediction after postoperative AED withdrawal in children – manuscript, figures & tables

2
3 Factors predicting seizure recurrence were: (higher) age at withdrawal, (shorter) time to AED
4
5 reduction, multifocal MRI abnormalities, interictal epileptiform discharges on EEG, and
6
7 incomplete resection of the anatomical lesion (Table 1, Figure 1); these factors combined into a
8
9 prediction model had an adjusted concordance-statistic of 0.68 (95% CI 0.68-0.69).
10
11

12
13
14 Factors predicting seizure-freedom at final follow-up were: seizure frequency before surgery,
15
16 (lower) number of AEDs used at time of surgery, and complete resection of the anatomical
17
18 lesion (Table 1, Figure 1); these factors combined into a prediction model had an adjusted
19
20 concordance-statistic of 0.73 (95% CI 0.72-0.75).

Individualized outcome prediction after postoperative AED withdrawal in children – manuscript, figures & tables

Discussion

We developed a prognostic tool to predict the seizure outcome after AED withdrawal in children who became seizure-free through epilepsy surgery, based on preselected factors that were identified through systematic review of the literature. The nomograms and the web-based tool, developed on a dataset from 766 children, are clinically useful when considering AED withdrawal in an individual patient. The predicted outcomes can serve as a basis to counsel children and caregivers when balancing the risks and benefits of AED withdrawal. The selected predictors are different between the two models. Interestingly, four predictors of seizure recurrence were not predictive of eventual seizure outcome: the timing of AED withdrawal – as revealed in the original *TimeToStop* study report⁶ –, the findings of pre-operative MRI, the age at withdrawal and postoperative EEG abnormalities. Two factors were only related to eventual seizure outcome: the pre-operative seizure frequency had a u-shaped relation with seizure outcome, with the lowest and highest seizure frequencies related to lower chances of eventual seizure-freedom, and the number of AEDs before surgery which showed a linear relation with the outcome. The only factor predictive of both outcomes was the completeness of resection: incomplete resection of the anatomical lesion increased the hazard of seizure recurrence by factor 2.5 and decreased the hazard of eventual seizure-freedom by factor 4.

Model performance in terms of discrimination was best for predicting eventual seizure-freedom, with an adjusted c-statistic of 0.73. The calibration plot for this model shows that it is able to accurately identify a small proportion with increased risk, where most patients have a predicted chance between 95% and 100% of being seizure-free for at least one year at an

1 Individualized outcome prediction after postoperative AED withdrawal in children – manuscript, figures & tables

2
3 average follow-up duration of six years after start of AED withdrawal. For predicting seizure
4
5 recurrence, the adjusted c-statistic of 0.68 shows reasonable discriminatory ability of the
6
7 model.
8
9

10
11 The current analysis has several limitations. First, although the analysis was performed on a
12
13 Europe-wide multicenter cohort and bootstrap-samples were used to correct for overfitting,
14
15 model performance should ideally also be tested in an external validation cohort. Second, one
16
17 of the preselected potential predictors, 'postoperative seizures', was not tested because none
18
19 of the patients with this factor experienced seizure relapse. Although no parameters could be
20
21 estimated, none of these 13 patients relapsed and six out of eleven patients (55%) were
22
23 successful at discontinuing AEDs, which is similar to the 48% in the complete cohort. Therefore,
24
25 the current data do not indicate an increased risk for patients with postoperative seizures, once
26
27 it has been decided to withdraw AEDs. However, the time to reduction was almost twice as
28
29 long for these patients, indicating that they had a substantial longer period of seizure-freedom
30
31 after the initial post-surgical relapse before reduction of AEDs. Lastly, it is important to realize
32
33 that postoperative seizure relapse risk has never been compared between patients who do, and
34
35 those who do not withdraw medication, in a prospective randomized manner. Our data, and all
36
37 cohort studies reporting on post-withdrawal relapse rates, only included a selection of patients
38
39 in whom the treating physician deemed it safe to start AED withdrawal. It cannot be excluded
40
41 that recurrence rates, predicted by the current model, are somewhat higher when applied in a
42
43 total cohort of unselected children who underwent epilepsy surgery. Therefore, the risk
44
45 predictor is most reliably applied in patients in whom physicians already consider withdrawal of

2
3 medication, but want to balance its risks and benefits to better counsel the individual patient
4
5 and his or her caregivers.
6
7

8
9 In conclusion, two prognostic models with moderate to good discriminative performance were
10
11 created and converted to a clinically useful tool to predict the individual risk of seizure
12
13 recurrence and eventual seizure-freedom, for children after epilepsy-surgery.

Individualized outcome prediction after postoperative AED withdrawal in children – manuscript, figures & tables

A. Predicting seizure recurrence after AED withdrawal

in children who are seizure-free after epilepsy surgery

Instructions

Determine individual risk in three steps:

1. For every variable on the left, count the points given at the top.
2. Add the points to a total score
3. Determine associated risk of seizure recurrence, seizure-freedom and cure

B. Predicting long-term seizure-freedom after AED withdrawal

in children who are seizure-free after epilepsy surgery

Figure 1. Nomograms predicting the outcome of AED withdrawal in seizure-free children after epilepsy surgery

Two nomograms predicting seizure outcomes of AED withdrawal, based on the models presented in table 1. (A) prediction of seizure recurrence in the first 2 and 5 years and (B) prediction of seizure-freedom (seizure-free for at least one year) at six years after surgery. (C) and (D) are the respective calibration plots. Predicted probabilities are plotted against the observed proportions for the 766 patients in the analysis, divided into groups of k=100. Alignment on the grey diagonal indicates good calibration, large deviation indicates worse calibration.
