ABSTRACT

Using an advanced computational methodology implemented in CP2K, a non-local PBE0-TC-LRC density functional and the recently implemented linear response formulation of the Time-dependent Density Functional Theory equations, we test the interpretation of the optical absorption and photoluminescence signatures attributed by previous experimental and theoretical studies to O-vacancies in two widely used oxides—cubic MgO and monoclinic (m)-HfO₂. The results obtained in large periodic cells including up to 1000 atoms emphasize the importance of accurate predictions of defect-induced lattice distortions. They confirm that optical transitions of O-vacancies in 0, +1, and +2 charge states in MgO all have energies close to 5 eV. We test the models of photoluminescence of O-vacancies proposed in the literature. The photoluminescence of V²⁺O centers in m-HfO₂ is predicted to peak at 3.7 eV and originate from radiative tunneling transition between a V⁺O center and a self-trapped hole created by the 5.2 eV excitation.

I. INTRODUCTION

Oxygen vacancies strongly affect physical and chemical properties of oxides and have been studied extensively both experimentally and theoretically.1-4 Experimental identification of such defects in bulk materials often relies on the interpretation of recorded optical absorption, photo-luminescence, and electron paramagnetic resonance spectra. Surprisingly, spectroscopic signatures of O vacancies in different charge states are not well established even in case of the simplest oxides, such as MgO. This complicates the verification of existence of O vacancies as well as models and hypothesis attributed to effects of their presence. In this paper, we test the interpretation of optical absorption and photoluminescence (PL) signatures attributed in the literature to O vacancies in two widely used metal oxides—cubic MgO and monoclinic (m)-HfO₂.

MgO has long been studied as a model wide bandgap oxide with numerous technological applications. Extensive experimental studies have been carried out of defects in MgO and particularly O-vacancy (also known as an F center).5-10 Theoretical studies, however, still struggle to give reliable insights into the optical spectra of different charge states of this defect. For example, theoretical models still continue to disagree on the exact positions of optical absorption peaks of neutral and positively charged vacancies. The first optical absorption peaks of the neutral and +1 charged oxygen vacancies (V⁰₀ and V⁺₀ centers) occur at very similar energies: 5.01 and 4.96 eV, respectively. 11 These peaks are difficult to resolve both experimentally and in theoretical calculations. Ab initio cluster model calculations of V⁰₀ and V⁺₀ defects 11 predicted
The optical excitation energy for the \( V_{O}^{0} \) defect, however, was not improved. It was therefore concluded that much larger basis sets are necessary for the accurate prediction of the optical absorption spectrum. In both of these studies, only excitations in the alpha spin channel were reported for the \( V_{O}^{0} \) center. However, there are, in fact, two types of optical excitation in the \( V_{O}^{0} \) center (see Fig. 1): a type-V transition into a higher state located close to the bottom of the conduction band (CB) in the \( \alpha \)-spin channel and a type-III transition from the defect-induced valence band (VB) states into the unoccupied state associated with the \( V_{O}^{0} \) center in the \( \beta \)-spin channel.

The \( \beta \) channel excitation was suggested in previous theoretical and experimental studies\(^{13,14} \) as a possible origin of the 5 eV absorption peak. Interestingly, both the \( \alpha \) and \( \beta \) channel excitations (type V and type III, correspondingly) in the \( V_{O}^{0} \) center are predicted to be close to 5 eV. Thus, all three optical absorption peaks associated with \( V_{O}^{0} \) and \( V_{O}^{1} \) centers have very close energies. A qualitative difference between \( \alpha \) and \( \beta \) spin excitation for the \( V_{O}^{0} \) center, however, is that \( \beta \) channel excitations should be associated with the release of holes into the valence band (VB). It has been shown that, when exciting MgO crystals with 5 eV light, a 2.3 eV absorption band also develops, which is associated with holes trapped on V-type centers.\(^{13,14} \)

Recent periodic Density Functional Theory (DFT) calculations\(^{13} \) account for different spin channel excitations in MgO using many-body perturbation theory in the G0W0 approximation and the Bethe-Salpeter approach. These calculations predicted the existence of a 3.6 eV absorption band in the \( V_{O}^{0} \) center (in addition to the known 5 eV band in the \( \alpha \) channel), which could be used to distinguish between the \( V_{O}^{0} \) and \( V_{O}^{1} \) centers. Thus the position and nature of optical absorption peaks of \( V_{O}^{0} \) and \( V_{O}^{1} \) centers in MgO remain controversial. They are revisited and discussed in more detail in Sec. III B.

MgO also has a photoluminescence (PL) band at 2.3 eV attributed to the \( V_{O}^{0} \) center.\(^{5-10,16} \) The nature of this luminescence has been discussed based on theoretical and experimental data in Refs.\(^{16,17} \) but has not been confirmed by many-electron calculations. These models are tested and discussed in detail in Sec. III C.

\( \text{HfO}_2 \) is another topical oxide with many properties attributed to O vacancies. This high dielectric permittivity oxide is being used both as a gate dielectric in modern transistors and as a reducible oxide in memory cells.\(^{15-19} \) The existing and newly generated oxygen vacancies in \( \text{HfO}_2 \) have been implicated in degradation of these devices and play the central role in the electroforming process in Resistive Random Access Memory (RRAM) devices.\(^{20-23} \)

Again, spectroscopic signatures of these defects are still controversial.

Experimentally, there is a well characterized 2.7 eV photoluminescence peak\(^{24-26} \) associated with a 5.2 eV absorption peak. The optical transitions for all five charge states of the oxygen vacancy in \( \text{m-HfO}_2 \) were calculated in a DFT study using both periodic and embedded cluster methods and Time-dependent DFT (TD-DFT) for calculating optical transition energies.\(^{26} \) These calculations predicted the absorption energy of the +2 charged oxygen vacancy \( (V_{O}^{2+}) \) defect at 4.94 eV, which is appreciably close to the 5.2 eV absorption peak. This provided evidence that the \( V_{O}^{2+} \) defect may be responsible for the 5.2/2.7 eV absorption/PL spectrum. Other experimental work on hafnia films has also connected this luminescence peak to oxygen vacancies. In a photoluminescence study,\(^{25} \) the 5.2 eV absorption and the 2.7 eV luminescence bands were interpreted as emerging from neutral (rather than positively charged) oxygen vacancies. Furthermore, another absorption/emission line—a 3.66 eV PL excited at 4.4 eV and 5.4 eV—has also been detected.\(^{27} \) The predicted optical absorption energy for the neutral vacancy is approximately 3.2 eV.\(^{26} \) This corresponds to an electron being excited out of a doubly occupied vacancy state [which has its Kohn-Sham (KS) level in the middle of the bandgap] into an unoccupied state at the bottom of CB (type V excitation in Fig. 1). These calculations also predict similar positions for absorption peaks of \( V_{O}^{1+}, V_{O}^{0}, \) and \( V_{O}^{1} \) defects, which all have occupied states at similar energies in the bandgap.

Thus, rather surprisingly considering the amount of research which went into studies of these two materials, their optical absorption and photoluminescence (PL) spectra are far from being understood. Predictions of positions of defect optical absorption and PL peaks rely on several factors: accuracy of calculations of defect-induced lattice relaxation, which often requires large periodic cells or clusters; positions of defect levels should be accurately reproduced, which requires using non-local density functionals; and techniques used to calculate optical excitation energies.
Satisfying all these requirements is challenging, and compromises are often made in favor of one of the variables. For example, small periodic cells are used to afford more computationally demanding calculations using the GW approximation and the Bethe–Salpeter approach for calculating optical spectra. More efficient but less accurate local density approximation (LDA) calculations are used to optimize the defect geometry.

Here we attempt to satisfy all the requirements by using an advanced computational methodology implemented in CP2K, a non-local PBE0-TC-LRC density functional and the recently implemented linear response (LR) formulation of the TD-DFT equations. These are described in detail in Sec. II and in the Appendix. Using this method, within the adiabatic approximation, we calculate the optical transition energies for the 0, +1, and +2 charged O vacancies in MgO and m-HfO$_2$ and estimate the photoluminescence energies for the V$_{O}^0$ and V$_{O}^2$ centers in MgO and m-HfO$_2$. The results emphasize the importance of accurate predictions of defect-induced lattice distortions. They confirm that optical transitions of O-vacancies in 0, +1, and +2 charge states in MgO all have energies close to 5 eV. We qualitatively confirm the model proposed to explain the nature of 2.3 eV PL in MgO in Refs. 16 and 17. The PL at 3.7 eV of V$_{O}^2$ centers in m-HfO$_2$ is predicted to originate from radiative tunneling transition (RTT) between a V$_{O}^0$ center and a self-trapped hole.

II. METHODOLOGY

A. Computational details

All simulations were carried out using periodic boundary conditions and the implementation of DFT in the CP2K software package. These calculations sample the Brillouin zone only at the $\Gamma$ point. To check the dependence of the results on the supercell size, the 216, 512 and 1000 atoms supercells were used for MgO, and 96 and 324 atoms supercells for m-HfO$_2$. Since we consider the 96 atom cell to be too small, we only analyze HfO$_2$ defects and optical transitions for the 324 atom cell.

Charged defects in the periodic model are calculated using the neutralizing jellium background, as implemented in CP2K. In this paper, we are mainly concerned with optical excitations of defects in particular charge states rather than their formation energies and transition levels, where charge corrections as well as potential alignment are important. TDDFT calculations include KS orbital energy differences, which are affected by the cell size as well as the extent of lattice distortion induced by charged defects. These effects are checked using periodic cells of increasing sizes.

The PBE0-TC-LRC exchange–correlation (XC) functional was used with an exact exchange contribution of 32.5% for the MgO calculations and 25% for the HfO$_2$ calculations. This functional is based on ordinary PBE0; however, HF exchange is only used for ranges up to a selected “truncation radius.” Beyond the truncation radius, a long range correction (based on the spherically averaged PBE exchange hole) is applied. In this work, we use 6 Å for the truncation radius in MgO and 4 Å in HfO$_2$.

The Goedecker-Teter-Hutter (GTH) pseudopotentials and GTH MOLOPT basis sets were used for all atom species. In our setup, Mg has 2 valence electrons, whereas Hf and O both have 6. All periodic cells had lattice parameters and optimized geometry such that forces were smaller than 0.023 eV/Å. The effect of oxygen vacancies on the local structure was simulated by re-optimizing the cell geometry after the deletion of an oxygen atom. Lattice parameters were kept constant during optimization of the defective cells. Since MgO has an FCC structure, all oxygen atoms in the periodic cell are equivalent and it is not necessary to sample different sites. In m-HfO$_2$, O atoms can be either 3- or 4-coordinated by Hf ions. In this work, we focus only on O vacancies at 3C sites. Positive or negative oxygen vacancies were simulated by removal or addition of electrons from the defective cell and then re-optimizing the geometry.

To calculate optical transition energies and oscillator strengths, we use the well established linear response formulation of the TDDFT within the local adiabatic approximation. In this approximation, the XC-functional is simply one of the usual XC-functional used for ground state DFT calculations. The detailed description of mathematical expressions implemented in CP2K is given in the Appendix.

The calculation of Hartree-Fock electron-repulsion integrals (ERIs) greatly increases the computational cost of hybrid functionals and renders the ground state DFT and TDDFT calculations infeasible for the system sizes considered here. For this reason, it is necessary to employ the auxiliary density matrix method (ADMM). This approximation utilizes a smaller and faster converging basis set, greatly speeding up the calculation of HF exact exchange. This allows us to use large supercells, which means we can more fully represent the structural relaxation induced by the presence of vacancies. Reducing the basis set quality can introduce errors in the HF exchange calculations. The key assumption of ADMM is outlined in Sec. II B.

B. Auxiliary density matrix method

In ground-state KS-DFT, the exact exchange energy, which is an essential component of hybrid XC-functional, is expressed in terms of a density matrix $P_{\mu\nu|\lambda\sigma}$

$$E_{KS}^H[P] = \sum_{\mu\nu|\lambda\sigma} P_{\mu\nu|\lambda\sigma} (\mu\nu|\lambda\sigma).$$

and Electron Repulsion Integrals (ERIs) over Gaussian basis functions $\{\xi\}$.

$$(\mu\nu|\lambda\sigma) = \int \chi_{\mu}^*(\mathbf{r})\chi_{\nu}^*(\mathbf{r})\frac{1}{|\mathbf{r} - \mathbf{r}'|} \chi_{\lambda}(\mathbf{r}')\chi_{\sigma}(\mathbf{r}') d\mathbf{r} d\mathbf{r}'.$$  

The number of such integrals grows with the total number of atomic basis functions to the fourth power in a naïve implementation that quickly becomes a bottleneck. However, the majority of these integrals are negligible. In particular, the inner product of two Gaussian functions centred on different atoms exponentially decays with the distance between these atoms. This effectively means that the number of non-negligible ERIs scales quadratically with the system size for a given basis set.
To take advantage of this fact, CP2K screens ERIs based on the Cauchy-Schwarz inequality,

$$\langle \mu | \nu \rangle_{\sigma} \leq \sqrt{\langle \mu | \mu \rangle_{\sigma} \langle \nu | \nu \rangle_{\sigma}}$$

and ignores the integrals which are less than the given threshold. Screening based additionally on the size of the density matrix element of the pair of orbitals in the ground state wave function can further reduce this to linear scaling. However, even in this case, evaluation of ERIs still remains a challenging task due to a large prefactor. This prefactor becomes much larger when the basis set is augmented with diffuse functions because these functions have a slower long-range decay. This problem also affects the MOLOPT basis sets commonly used in CP2K, as they contain significant numbers of (contracted) diffuse basis functions.

The Auxiliary Density Matrix Method (ADMM) addresses this problem by computing ERIs using a small auxiliary basis set with rapidly decaying basis functions \{\hat{\chi}\}. An approximate auxiliary density matrix \(\tilde{P}\) is then constructed by fitting the density matrix in the primary basis set \(P\),

$$\tilde{P} = O \hat{P} O^T,$$

using a projector from the primary basis set onto the auxiliary basis set,

$$O = \hat{S}^{-1} U,$$

$$\hat{S}_{\mu \nu} = \langle \hat{\chi}_\mu | \hat{\chi}_\nu \rangle, \quad U_{\mu \nu} = \langle \chi_\mu | \chi_\nu \rangle.$$

Optionally, the ground-state auxiliary density matrix can be purified using a number of techniques to ensure that all properties of a true density matrix are met. We have not implemented purification for use with TDDFT methods, as a response density matrix \(P^{(0)}\) which appears in Eq. (1) instead of the ground-state density matrix—does not satisfy all conditions for a pure density matrix (see the Appendix for further details).

ADMM also assumes that the difference between exact-exchange energies computed using primary and auxiliary basis sets has (semi-)local nature and thus can be well described using some reference LDA or generalised gradient approximation (GGA) exchange functional \(E^{\text{DFT}}\). It naturally leads to the trivial expression for the approximate exact-exchange energy in the primary basis set,

$$E^{\text{HF}}_x[P] \approx E^{\text{HF}}_x[\tilde{P}] + (E^{\text{DFT}}_x[P] - E^{\text{DFT}}_x[\tilde{P}]).$$

Differentiation of the above expression with respect to the density matrix gives the following contribution to the Kohn-Sham matrix:

$$K^{\text{HF}}_x \approx F^{\text{DFT}}_x + O^T (K^{\text{HF}}_x - F^{\text{DFT}}_x) O,$$

where

$$F^{\text{DFT}}_{\mu \alpha} = \int x_\mu^*(r) \chi_\alpha(r) d\mathbf{r},$$

$$F^{\text{DFT}}_{\mu \alpha} = \int \hat{\chi}_\mu^*(r) \hat{\chi}_\alpha(r) d\mathbf{r},$$

$$K^{\text{HF}}_{\mu \alpha} = \sum_{\sigma \sigma'} \tilde{P}_{\mu \sigma} (\mu \nu | \sigma \sigma') \chi_\nu(r) d\mathbf{r}.$$

and \(\chi_\nu(r)\) is the (semi-)local reference exchange potential as a functional of the electron density.

### III. RESULTS AND DISCUSSION

#### A. Properties of perfect crystals

We start from considering the bulk properties of MgO and m-HfO\(_2\). All calculations are performed using the Brilouin zone at the \(\Gamma\) point. The bandgap energies are calculated as the difference of Kohn-Sham (KS) energies and using TDDFT. The results shown in Tables I and II for MgO and m-HfO\(_2\), respectively, demonstrate good agreement of lattice parameters with experimental reports. However the band gap of HfO\(_2\) is slightly underestimated. We note that in both systems, the TDDFT calculated optical bandgap is lower than the KS bandgap. This is because, unlike in GGA-based TDDFT, in hybrid functional based TDDFT, there is electron-hole interaction. Excitation between delocalized band states creates an electron-hole pair which is confined within the simulation cell and thus has an artificial high electron-hole interaction energy. This explains why the difference between the KS and TDDFT bandgap is greatest for small simulation cells where the electron-hole pair is more confined and thus the electron-hole interaction is greater.

#### B. Optical transitions of O vacancies

The removal of a neutral oxygen atom in the MgO or m-HfO\(_2\) periodic cell leaves behind a neutral oxygen vacancy, \(V_0^O\). Two electrons localize on the vacancy (see Fig. 2). These localized electrons occupy two degenerate mid-gap levels (one state for each spin) which are located 4.45 eV below the conduction band minimum (CBM) in MgO and 3.3 eV below the CBM in HfO\(_2\). In general, the vacancy perturbs the electronic optical bandgap (BG) is calculated using TDDFT. Cell sizes are given in number of atoms.

Published under license by AIP Publishing
The wavefunctions of excited states calculated using TDDFT are linear combinations of determinants where $\Psi_i$ is a singly excited wave-function, whose $i$th occupied Molecular Orbital (MO) is replaced by the $i$th virtual MO (see the Appendix). Often one excitation $\Psi_i$ dominates and will be used to qualitatively represent the excited state in further discussion.

The lowest energy transition of the MgO $V_0^0$ defect has zero oscillator strength because the singly occupied defect state and the LUMO state dominating this transition have similar cubic symmetry (see Fig. 2) analogous to hydrogenic 1s and 2s orbitals. The next three higher energy transitions have equal excitation energies and are responsible for the main absorption peak seen in $V_0^0$ defects in MgO (Fig. 3(a)). They correspond to the excitation into a degenerate $\beta$–like state.

$V_0^0$ center in m-HfO$_2$ has lower symmetry and the TDDFT calculations predict a broader absorption spectrum with an onset at 2.5 eV and then with higher energy peaks at 3.0 eV and 3.5 eV. Also, unlike in MgO, the $V_0^0$ excitation in HfO$_2$ is from the vacancy state into the states delocalized at the bottom of the conduction band, hence much lower oscillator strengths of these transitions. The calculated spectra of the $V_0^0$ in HfO$_2$ are plotted in Fig. 3d. We note that the predicted transition energies are in good agreement with the results of embedded cluster calculations in Ref. 26.

In the +1 charge state, transitions in the $\alpha$ and $\beta$ spin channels are no longer equivalent. In MgO, the absorption energies in both spin channels have been predicted to be close to one another, making the interpretation of optical absorption spectra difficult. Here, however, we predict that the $\beta$ spin excitation has higher energy (Fig. 3b). This should lead to asymmetry in high energy part of the optical absorption spectrum of the $V_0^0$ center and can explain the asymmetric line shape observed in Ref. 7. There will also be qualitative differences between the two types of excitation. Excitations in the $\alpha$ channel will excite an electron from the gap state into CB states, similar to the $V_0^0$ defect. Excitations in the $\beta$ channel, however, will release holes into the valence band. It is then possible for these holes to be trapped onto V-centers.

We note that our results do not support the prediction that the $\beta$ absorption energy should be much lower than the $\alpha$ spin absorption energy ($\approx 3.6$ eV). It is possible that the 3.6 eV absorption band emerges due to constraint on the $V_0^0$ center relaxation imposed by small periodic cells used in Ref. 15. Indeed, charging the $V_0^0$ carbon to the +1 state but not allowing the structure to relax brings the main $\beta$–spin absorption energy down to 3.5 eV. This is not surprising as the defect-induced lattice distortion strongly affects the positions of quasi-local states in the valence band responsible for $\beta$ transitions. We therefore find that failure to allow the charged defect to fully relax can change absorption energies by as much as 2 eV.

In HfO$_2$, optical excitations in the $\alpha$ and $\beta$ spin channels have different energies. To illustrate why, we can look at the electronic structure of the $V_0^0$ defect in HfO$_2$. The alpha HOMO-LUMO separation is calculated to be 3.6 eV, whereas the beta HOMO-LUMO separation is...
FIG. 3. Optical absorption spectra of oxygen vacancies in MgO and m-HfO$_2$. (a) is the V$_{0}^{0}$ defect in MgO. There is strong absorption peaking at 4.85 eV. This corresponds to a transition between an s-like and a p-like states. (b) shows transitions in the V$_{0}^{+1}$ center in MgO. The lower energy absorption peaks at 4.70 eV and comes from excitation of an $\alpha$ spin electron in a gap-state into CB states. The higher energy absorption peaks at 5.26 eV and comes from excitation of electrons in VB states into the unoccupied state in the gap. (c) is the V$_{0}^{+2}$ defect in MgO. (d), (e), and (f) correspond to the V$_{0}^{0}$, V$_{0}^{+1}$ and V$_{0}^{+2}$ centers in m-HfO$_2$, respectively. All the transitions represented by (e) are from excitations in the alpha channel. Individual transitions (without smearing) are shown by delta functions, and in (f), these transitions are too small to be seen. The smeared spectra is plotted using Gaussian smearing of $\sigma$ = 0.2 eV. Calculated to be 5.6 eV (very close to the optical bandgap value). Thus, when irradiating HfO$_2$ with photons of sub-bandgap energy, we expect the V$_{0}^{+1}$ spectrum to be dominated by $\alpha$ spin transitions (transitions from the vacancy state into the CB states, i.e., type IV in Fig. 1). Indeed we predict that the first optical absorption peak occurs at 2.9 eV and corresponds to the transition of the alpha-spin electron from the gap-state into a quasi-local state in the CB. All the higher energy peaks up to bandgap energy also correspond to excitations of the $\alpha$-spin electron out of the gap-state and into higher energy CB states. Excitations in the $\beta$ spin channel are only attainable once we arrive at excitation energies comparable with the bandgap.

In both materials, the V$_{0}^{+2}$ defect produces an unoccupied state high in the valence band as well as resonant states in the CB (Fig. 1). In MgO, the optical absorption of the V$_{0}^{+2}$ center has been predicted to be close to the V$_{0}^{0}$ and V$_{0}^{+1}$ defects. It is dominated by transitions from the defect-induced states in the valence band into the LUMO defect state located close to the bottom of the CB (type III in Fig. 1). Therefore, all of the V$_{0}$ defects in MgO are predicted to have optical absorption peaks near 5 eV. This explains why it is so difficult to distinguish between different charge states of the V$_{0}$ defect in MgO using optical absorption experiments alone.

In HfO$_2$, the optical transition energies from the valence band into the V$_{0}^{+2}$ defect are comparable to the bandgap energy and are predominantly of type II in Fig. 1. Optical experiments conducted on HfO$_2$ have detected a 5.2 eV absorption peak which has been attributed to the presence of oxygen vacancies. We predict that the doubly positively charged oxygen vacancy (V$_{0}^{+2}$) has an optical absorption peak at 5.3 eV, which is in good agreement with this detected absorption band. We note that the position of the peak predicted in this work is at higher photon energy than 4.94 eV calculated in Ref. 26 using TDDFT in a relatively small embedded cluster. This is consistent with our observation that full account of defect-induced lattice distortion for charged defects is important for predicting correct optical absorption energies.

C. Photoluminescence energies

As was mentioned above, MgO has a well-established PL band at 2.3 eV attributed to the V$_{0}^{0}$ center. The lifetime of this luminescence is much longer than that for the V$_{0}^{+1}$ center, which is caused by a single-electron transition in the doublet state. Therefore the 2.3 eV luminescence of the V$_{0}^{0}$ center could be due to a partially allowed 2s $\rightarrow$ 1s type
and/or triplet-to-singlet transition. The kinetics of this PL is, however, much more complicated than that of the V$_{O}^{2-}$ center in CaO, where the lowest relaxed excited state has been shown to have a tetragonal (100) triplet state with fast spin-lattice relaxation (see, for example, Ref. 41). The PL kinetics in MgO is strongly affected by the presence of H and other impurities and depends on sample preparation. 8,16 Semi-empirical calculations suggest that tetragonal singlet and triplet states are both located very close to the bottom of the CB and that there are two minima in the relaxed excited state corresponding to $^{3}T_{1u}$ and $^{1}A_{1g}$ configurations, respectively. The predicted PL energies corresponding to transitions from these two minima are equal to 2.9 eV and 2.2 eV, respectively. The PL peaking at 2.9 eV has been observed experimentally but has an excitation energy at about 7 eV. It has been concluded that the PL peaks at 2.3 eV and 2.9 eV may involve both transitions intrinsic to the V$_{O}^{2-}$ center and those caused by electron transfer from impurities. 8,16 We note that the dynamics of similar PL of F centers in alkali halides has been studied in detail. 43 In that case, the transition is allowed due to mixing of 2s and 2p terms, with 2s having the lower energy in the relaxed excited state. 43

To shed more light on the nature of excited states, we have calculated the triplet excited states of the V$_{O}^{2-}$ center in MgO using the so-called ∆SCF method. This computational procedure employs a non-Aufbau occupation of the triplet state in a dielectric to converge the KS equations to an excited state. 44,59 The total energy and geometry of the triplet excited state of a defect are calculated self-consistently. This approach allows us to predict defect geometries in the electronically excited state (the feature still unavailable in TDDFT in CP2K). The lowest energy triplet state has $^{1}A_{1g}$ symmetry, and the calculated luminescence energy from this state is 2.0 eV. A higher energy triplet state has a geometry formed from a combination of $A_{1g}$ and $T_{2g}$ displacement modes. The calculated PL energy from this state is 2.9 eV. Thus our calculations support the PL model suggested in earlier studies 8,16 with surprising agreement of calculated PL energies.

We used the same approach to investigate the luminescence of the neutral oxygen vacancy in m-HfO$_{2}$. In the case of optical excitation of the V$_{O}^{2-}$ defect, the electron-hole pair remains bound to the vacancy. The predicted triplet–singlet PL energy is 0.8 eV.

The situation is, however, more intriguing in the case of the V$_{O}^{2-}$ center. It produces an unoccupied state inside the gap close to the bottom of the CB as well as quasi-local states in the VB and CB in both MgO and m-HfO$_{2}$. In alkali halides, a singly positively charged anion vacancy (also called an α-center) has a qualitatively similar electronic structure and a characteristic luminescence, which is close in energy to the exciton luminescence (the so-called α-luminescence) and is attributed to exciton perturbed by the vacancy. 45 The relaxed excited state of this center can be also viewed as an electron transferred into the vacancy and a hole trapped next to the vacancy. 46 Such luminescence has not been observed for the V$_{O}^{2-}$ center in MgO because free excitons in MgO are very mobile and get trapped by impurities. Since excitons and holes have been suggested to self-trap in m-HfO$_{2}$, one could expect creation of α-type luminescence in this material. Recent experiments suggest that 3.6 eV luminescence excited by 5.3 eV photons could be due to charged vacancies in m-HfO$_{2}$.

Using the ∆SCF method, we investigated the triplet excited state of the V$_{O}^{2-}$ defect in HfO$_{2}$. It is found that the relaxed triplet configuration of the V$_{O}^{2-}$ center has an electron localized into the vacancy (producing a V$_{O}^{2-}$ center) and a hole localized in a polaron state elsewhere in the supercell. Holes have been predicted to self-trap in m-HfO$_{2}$ at low temperatures. 48,50 Due to repulsion with the positively charged vacancy, the hole cannot sit close to the vacancy—the closest stable separation we find between the hole polaron and the vacancy is approximately 5 Å (see Fig. 4). Therefore the localized hole and vacancy can be viewed as two separated defects. In such a system, luminescence due to electron–hole recombination can occur when the electron in the V$^{3+}$ defect tunnels into the hole polaron via a radiative tunneling transition (RTT). The RTT recombination luminescence of spatially well-separated electron and hole defects has been studied in semiconductors 51 and ionic crystals. 52 It usually occurs between ground electronic states of donor and acceptor.

We predict the photon energy of this emission to be 3.7 eV. Unlike in semiconductors, the emission energy does not depend on the defect separation in the range of up to 11 Å (this upper limit originates in the finite size of the supercell) due to dielectric screening in the high-k material. In Ref. 53, a range of luminescence peaks between 2.0 and 3.7 eV, attributed to oxygen vacancies, have been detected at approximately 7 K using cathodoluminescence and optical luminescence. In another optical experiment, conducted at 10 K, weak emission in the range of 2.2 to 3.6 eV has been detected. A recent study 57 also found luminescence peaking near 3.6 eV, again linked to oxygen vacancies. These results are consistent with the optical absorption of the V$^{2-}$ defect and the optical properties of HfO$_{2}$.

FIG. 4. The relaxed triplet configuration of the V$_{O}^{2-}$ defect. An electron localises around the vacancy (to create a V$_{O}^{2-}$ defect) and a hole self-traps elsewhere in the lattice. A range of separations between hole and vacancy are possible. Here, the closest separation configuration is shown. Transparent surfaces show the wavefunction of the hole (orange) and electron (blue). The isosurface value is 0.007. The nearest neighbor atoms of each defect are highlighted.
predicted RTT luminescence energy. However, further studies are required to elucidate the nature of experimentally observed peaks.

IV. CONCLUSIONS

To conclude, we used a newly implemented TDDFT algorithm in CP2K to conduct optical absorption calculations on oxygen vacancies in MgO and HfO$_2$. Using a range of periodic cells, we demonstrate that failure to properly describe the geometric structure of a defect significantly affects the predicted absorption energies, potentially by several eV. We confirm the existing models of the nature of optical absorption and photoluminescence of O vacancies in MgO and HfO$_2$ and predict that the PL at 3.7 eV in HfO$_2$ and photoluminescence of O vacancies in MgO and HfO$_2$ predicted absorption energies, potentially by several eV. We use the following index convention: i and j label occupied orbitals, a and b stand for virtual orbitals, and $\sigma$ and $\tau$ refer to spin components. Besides, the quantity $\epsilon_{ci\sigma}$ stands for the i-th Kohn-Sham orbital energy, and $f_{xc;\sigma\tau}(r,r')$ is a response XC-kernel. The explicit expression for the $A^{\text{XC}}$ term in Eq. (A2) is given in the adiabatic approximation which postulates independence of the XC-functional on time. As such, XC-kernel becomes the second functional derivative of the XC-functional ($E_{xc}$) over the ground-state electron density ($\rho$)\textsuperscript{(0)}\textsuperscript{56}

$$f_{xc;\sigma\tau}(r,r') = \frac{\delta^2 E_{xc}[\rho]}{\delta \rho_{\sigma\tau}(r') \delta \rho_{\sigma\tau}(r)}.$$  \textsuperscript{(A6)}

It is important to note that in case of a hybrid exchange functional, the exact-exchange term is excluded from the XC-functional prior taking its functional derivative. For example, in case of the ordinary PBE0 XC-functional\textsuperscript{56} which contains 100% PBE correlation, 75% PBE exchange, and 25% exact-exchange energies, only the first two terms contribute toward the XC-kernel.

As is customary, we also use the Tamm-Dancoff approximation (TDA)\textsuperscript{57} which amounts to setting all the elements of the matrix $A$ in Eq. (A1) to zero. This simplifies the LR-TDDFT equation by reducing it to a standard Hermitian eigenproblem,

$$AX_p = \omega_p X_p.$$ \textsuperscript{(A7)}

We use the block Davidson method\textsuperscript{58} to solve this eigenproblem, as the matrix $A$ itself is a diagonally dominant one and only few excited states are typically in interest.

A significant advantage of the Davidson algorithm follows from its iterative nature. The algorithm approximates target eigenvectors by iteratively refining a set of trial vectors $X_p$—one vector for each excited state $p$ in question—and only the action of the response operator on these vectors $AX_p$ needs to be known. In our implementation, we use trial vectors in form of contracted response orbitals $\phi_{\text{LUMO}}^{(0)}(r)$, which is a linear combination of virtual Kohn-Sham orbitals $\phi_{a;\sigma\tau}(r)$,

$$\phi_{\text{LUMO}}^{(0)}(r) = \sum_{u} X_{u;p} \phi_{a;\sigma\tau}(r).$$ \textsuperscript{(A8)}

obtained from solving the ground-state KS-DFT equations. The squared contraction coefficients $|X_{u;p}|^2$ thus can be thought as a probability of an electron transition between the ith occupied and ath virtual KS orbitals.
By analogy with occupied ground-state KS orbitals $\phi_{i,\sigma}$, the contracted response orbitals are expanded as a linear combination of atomic basis functions $\{|\chi_{\lambda}\}$,

$$\phi_{i,\sigma}(\mathbf{r}) = \sum_{\mu=1}^{N} C_{i\mu,\sigma}^{(0)} \chi_{\mu}(\mathbf{r}), \quad \phi_{i,\sigma}^{(1)}(\mathbf{r}) = \sum_{\mu=1}^{N} C_{i\mu,\sigma}^{(1)} \chi_{\mu}(\mathbf{r}),$$

(A9)

subject to orthogonality conditions,

$$\text{Tr}\left(C_{i\sigma}^{(0),T} S_{\text{per}} C_{i\sigma}^{(0)}\right) = 0,$$

(A10)

$$\text{Tr}\left(C_{i\sigma}^{(0),T} S_{\text{per}} C_{i\sigma}^{(0)}\right) + \text{Tr}\left(C_{i\sigma}^{(0),T} S_{\text{per}}^{(1)} C_{i\sigma}^{(0)}\right) = \delta_{p,q},$$

(A11)

where $S_{\mu\nu} = \langle \chi_{\nu}|\chi_{\mu}\rangle$ is the overlap matrix and $\delta_{pq}$ is the Kroenecker delta. The calculation of the action of the response operator on trial vectors, expressed in the atomic basis set, is then performed in the following steps, which are essentially the same steps as required for building the Kohn-Sham matrix in ground-state DFT using the Gaussian and plane wave method:28

1. For every spin component $\sigma$, construct the response density matrix,

$$P_{\mu\nu}^{(0)} = \frac{1}{2} \left( C_{\sigma,\sigma}^{(0),T} + C_{\sigma,\sigma}^{(0)} C_{\sigma,\sigma}^{(0),T} \right).$$

(A12)

The initial guess is formed from energetically ordered single orbital excitations. Note that the response density matrix is not a pure one, as it does not fulfill the idempotent property,

$$P_{\mu\nu}^{(0)} S P_{\mu\nu}^{(0)} \neq P_{\mu\nu}^{(0)}.$$ 

Map the response density onto a real-space grid $P_{\mu\nu}^{(0)} \rightarrow \rho_{\mu\nu}(\mathbf{r})$ and the corresponding reciprocal-space grid by performing the fast Fourier transformation (FFT),

$$\rho_{\mu\nu}^{(0)}(\mathbf{G}) = \text{FFT}[\rho_{\mu\nu}^{(0)}(\mathbf{r})].$$

2. Compute the energy difference term,

$$A^{(0)} E_{\mu\nu}^{(0)} = F_{\sigma\rho}^{(0)} C_{\rho\sigma}^{(0)} - \epsilon_{\sigma\rho} S_{\mu\nu}^{(0)},$$

(A13)

where $F_{\sigma\rho}$ and $S$ are Kohn-Sham and overlap matrices, respectively, and $\epsilon_{\sigma\rho}$ is a diagonal matrix of Kohn-Sham orbital energies.

3. Compute the Coulomb term by

(a) solving the Poisson equation on the reciprocal grid, $\rho_{\mu\nu}^{(0)}(\mathbf{G}) \rightarrow \phi_{\mu\nu}^{(0)}(\mathbf{G})$;

(b) calculating components of the electrostatic potential on the real-space grid using the inverse FFT, $\phi_{\mu\nu}^{(0)}(\mathbf{r}) = \text{FFT}^{-1}[\phi_{\mu\nu}^{(0)}(\mathbf{G})]$.

4. Compute the adiabatic XC term by evaluating the integral,

$$f_{\text{xc}}(\mathbf{r}) = \sum_{\tau=\pm} \eta_{\tau} \int f_{\text{xc,}\tau}(\mathbf{r},\mathbf{r}') \rho_{\mu\nu}^{(0)}(\mathbf{r}) d\mathbf{r'},$$

(A14)

on the real-space grid. The scaling factors $(\eta_{+}, \eta_{-})$ are equal to $(2, 0)$ or $(1, -1)$ for singlet and triplet states computed using spin-unpolarised electron density, or $(1, 1)$ otherwise.

5. Transform the sum of electrostatic potential and the XC term from the grid representation into a matrix representation in the atomic basis set by evaluating expectation values,

$$\left(A^{(0)} C_{\mu\nu} + A^{\text{XC}} C_{\mu\nu}^{(0)} \right)_{\mu\nu} = \int \phi_{\mu\nu}^{(0)}(\mathbf{r}) \phi_{\mu\nu}^{(0)}(\mathbf{r}) f_{\text{xc}}(\mathbf{r}) d\mathbf{r}.$$ 

(A15)

6. Using precomputed ERIs over atomic basis functions $(\mu\nu, \lambda\xi)$, compute matrix elements of the exact-exchange operator,

$$(K_{\mu\nu})_{\mu\lambda} = \sum_{\nu\xi}(\mu\nu|\lambda\xi) \left(\rho_{\mu\nu}^{(0)}\right)_{\lambda\xi}. \quad \text{(A16)}$$

The exact-exchange action term is then calculated as a matrix product scaled by the amount of the exact exchange,

$$c_{\text{HFX}}^2 E_{\mu\nu}^{(0)} + c_{\text{HFX}} K_{\mu\nu} C_{\mu\nu}^{(0)}.$$  

(A17)

7. When combined with ADMM (see Sec. II B), instead of the previous step, compute the matrix elements of the exact-exchange operator in an auxiliary basis set $\{|\bar{\chi}\}$ using the auxiliary density matrix $\bar{P}$ from Eq. (4),

$$(\bar{K}_{\mu\nu})_{\mu\lambda} = \sum_{\nu\xi}(\mu\nu|\lambda\xi) \left(\bar{P}_{\mu\nu}^{(0)}\right)_{\lambda\xi},$$  

(A18)

and then project the obtained matrix back to the primary basis set,

$$K_{\mu\nu} = O^T \bar{K}_{\mu\nu} O. \quad \text{(A19)}$$

Repeating steps 4 and 5 we also compute two compensation XC terms using a reference (semi-)local XC-functional in accordance with Eq. (8).

8. All components of the action matrix for the given response wave function (steps 2, 5, and 6) are then summed up. Once obtained for all excited states in question, these action matrices are then used in the block Davidson algorithm28 to compute residuals and to refine the response wave functions.

With no periodic boundary conditions, having the optimised response wave function for the th transition $\Psi_{\mu}$, one can compute the associated oscillator strength using the classic expression for dipole integrals in the “length” form,54

$$f_{\mu} = \frac{2}{3} \alpha_{\mu} \sum_{q=0}^{x,y,z} |\langle \Psi_{\mu}|q|\Psi_{0}\rangle|^2. \quad \text{(A20)}$$

The above expression can be recast in terms of contracted expansion coefficients,

$$f_{\mu} = \frac{2}{3} \alpha_{\mu} \sum_{q=0}^{x,y,z} \left|\text{Tr}[C_{\mu,\sigma}^{(0),T} C_{\mu,\sigma}^{(0)} Q_{\sigma\lambda}^{(0)}]\right|^2, \quad \text{(A21)}$$

where the matrix elements of the dipole operator in atomic basis set are

$$Q_{\mu\nu} = \langle \chi_{\mu}|q|\chi_{\nu}\rangle. \quad \text{(A22)}$$

and $C_{\mu\sigma}$ is a matrix of expansion coefficients of virtual Kohn-Sham orbitals $\phi_{i,\sigma}^{(0)}(\mathbf{r})$ in the atomic basis set. Using the
commutation relation between Hamiltonian and position operators

\[ [\hat{H}, \hat{r}] = -\nabla, \]  

(A23)

we can rewrite Eq. (A21) in the equivalent “velocity” form,

\[ f_p = \frac{2}{3} \omega_p \sum_{q=x,y,z} \left| \text{Tr} \left[ C_p^{(0)} \hat{T} \hat{C}^{\text{virt}} \left( W \otimes (\hat{C}^{\text{virt}}(r) \partial S / \partial q) \right) \right] \right|^2, \]  

(A24)

to make it suitable for periodic boundary conditions. Here \( W \) is the inverse energy difference matrix between all virtual \((a)\) and occupied \((i)\) Kohn–Sham orbitals,

\[ W_{ai} = (\epsilon_a - \epsilon_i)^{-1}, \]  

(A25)

\( \partial S / \partial q \) is a matrix containing the first partial derivative of overlap integrals along the \( q \) direction,

\[ \left( \frac{\partial S}{\partial q} \right)_{\mu\nu} = \langle \chi_\mu | \frac{\partial \chi_\nu}{\partial q} \rangle, \]  

(A26)

and the symbol \( \otimes \) denotes the element-wise (Hadamard) product.
