"Fifteen Minute Consultation: Obvious and Not-So-Obvious Mediastinal Masses"

Green K, Behjati S, Cheng D.

Objectives:

To present a structured approach to the management of a child with a mediastinal mass presenting to the emergency department

To raise awareness of presenting features of less-obvious mediastinal masses and to encourage consideration of mediastinal masses in differential diagnoses

Methods:

Review of the relevant literature and review of London Paediatric Cancer Network supportive guidelines and subsequent description of the approach to a child presenting with features suggestive of a mediastinal mass.

Conclusions:

A systematic approach to history taking, clinical examination, and investigation of a child presenting with a mediastinal mass will assist in the safe and timely management of children presenting when they are critically unwell. Anticipation of potential management complications and early transfer for ongoing management will improve patient outcomes and minimise morbidity.
15 Minute Consultation: Obvious and Not-So-Obvious Mediastinal Masses

Introduction

Mediastinal masses in children are a rare but life-threatening presentation. They are the most common chest mass in children, with the anterior mediastinum being the most common site\(^1\), and lymphomas being the most common cause\(^1-3\). Whilst some mediastinal masses may present with obvious symptoms and clinical signs and appear obvious on chest x-ray (CXR), such as in figure 1, many do not, as in figure 2 below. Children with anterior mediastinal masses are at significant risk of serious and potentially fatal complications at presentation, most commonly due to extrinsic compression of the airway, and obstruction to the venous return or obstruction of cardiac output. Not infrequently clinical symptoms may not correlate with radiological findings\(^1-7\). Airway obstruction has been reported in approximately 60% of patients presenting acutely with mediastinal masses\(^1\). Furthermore, one third of asymptomatic patients have a significant reduction in tracheal dimensions seen upon CT scanning\(^4\), with total consensus that sedation and general anaesthesia should be avoided and managed by experienced paediatric anaesthetists if considered essential\(^1-9\).

Anterior mediastinal masses are a paediatric medical emergency and should be considered a haematological/oncological emergency until proven otherwise, especially given that lymphomas (the most common cause of a mediastinal mass) can rapidly grow and progress over hours to days. Children should be managed by experienced paediatricians with a low threshold for escalating to paediatric intensive care.

Obvious and Not-So-Obvious Mediastinal Masses

Case 1: An ‘Obvious’ Mediastinal Mass

*Figure 1*- A clinical case of ‘obvious’ mediastinal mass seen on CXR presenting to the emergency department.
Case 2: A ‘Not-So-Obvious’ Mediastinal Mass

Figure 2- A clinical case of a ‘not-so-obvious’ mediastinal mass seen on CXR presenting to the emergency department.

THINK! Could you have mistaken Figure 2 for a pleural effusion?

Mediastinal masses often present atypically with a homogenous ‘white-out’ on CXR, and can easily be mistaken for more common diagnoses such as pleural effusions or a large opacification ie. pneumonia. Although more uncommon, always consider a mediastinal mass in an unwell patient with a ‘white-out’ on CXR, especially where there is a lack of classical symptoms of infection. Remember, a widened mediastinum on CXR cannot be attributed to normal thymus in children over 5 years.

History

All medical consultations should commence with a detailed paediatric history. This may immediately identify symptoms of a mediastinal mass, airway compromise or life-threatening neurological or cardiovascular compromise. More specific symptoms that may suggest a mediastinal mass are listed below in figure 3, but it is not uncommon for a mediastinal mass to be a surprise finding on CXR as they are often not as obvious at presentation as may be expected.
Examination

Respiratory signs are the most common presentation of a mediastinal mass, with up to 60% paediatric patients presenting with airway compromise.

In a life-threatening situation, children should be managed using an airway, breathing, circulation, disability/neurology approach as per APLS.

Mediastinal masses may present obviously or inconspicuously depending on the size and origin of the mass. A thorough full-systems paediatric examination should be performed, with specific attention given to the respiratory, cardiovascular, ear nose and throat (ENT) and neurological systems; carefully assessing for evidence of airway compromise, superior vena cava obstruction, cardiac or neurological compromise seen in less-obvious mediastinal masses.

The key obvious and less-obvious presenting signs of mediastinal masses are described in figure 4 below.

It is not unusual for mediastinal masses (typically T-cell lymphoma or leukaemia) to be associated with pleural and/or pericardial effusions, thus making the underlying mediastinal mass harder to identify. Such pleural effusions may be bilateral and may further compromise the child’s respiratory status, and should increase the clinicians suspicions of what may lie underneath.
Figure 4- Obvious and less obvious signs on clinical examination suggesting a mediastinal mass

Differentials of Paediatric Mediastinal Mass

There are a wide range of differential diagnoses for a child with a mediastinal mass, as summarised in figure 5.

Figure 5- Differential diagnoses of a mediastinal mass in a child

Causes of a homogenous ‘White Out’ or homogenous opacity on CXR

- Chest wall mass, e.g. Ewing’s sarcoma
- Consolidation
- Diaphragmatic hernia
- Diaphragmatic rupture
- Mediastinal mass
- Pleural effusion
• Pneumonectomy
• Pulmonary agenesis or hypoplasia
• Total lung collapse, eg. post endobronchial intubation

**Investigations**

Investigations in a child with mediastinal mass will be directed primarily by how unwell the child is and by the continuous assessment of the child’s airway status and any sign of airway, respiratory or neurological compromise. It is essential not to compromise the child’s safety to pursue clinical investigations.

The delivery of sedation or anaesthesia for a child with an anterior mediastinal mass can be fatal. This is due to the loss of muscle tone and the subsequent loss of the compensatory physical effort of maintaining the airway which occurs when sedated or unconscious. This process can result in an acute loss of airway patency which can be fatal even in the hands of an experienced anaesthetist. For this reason children with a suspected mediastinal mass should undergo sedation or anaesthesia only under the care of an experienced paediatric anaesthetist fully aware of the child’s situation, and if no other option is available.

As demonstrated in figure 6, there are surprisingly few essential investigations required to permit commencing emergency treatment for a mediastinal mass where haematological malignancy is suspected.
**Figure 6**—Recommended investigations and guidance on where and when to perform them in a child with suspected mediastinal mass

**Essential Diagnostic Investigations for Mediastinal Masses**

- **A baseline full blood count** should be performed and may indicate an underlying diagnosis of acute lymphoblastic leukaemia.

- **A blood film** should be performed to investigate for the presence of blasts.

- **Baseline bloods**—urea and electrolytes, urate, phosphate, liver function tests, and a coagulation screen should be performed prior to commencing treatment.

- **CXR**—erect anteroposterior (AP) and lateral CXRs should be performed to establish the size and location of the mediastinal mass and are adequate imaging prior to commencing emergency treatment in a child too unstable to have a CT chest at presentation. Figure 7 illustrates the anatomical division of the mediastinum on CXR.

**Figure 7**—Anatomical division of anterior, superior, middle and posterior mediastinum on lateral CXR
- **CT chest**, in patients without concerns for airway compromise and who are able to lie flat safely, is a helpful diagnostic investigation. However, where there are concerns for potential acute airway compromise and in patients who are unable to lie flat safely, cross-sectional imaging is not required as an essential investigation and should not be performed. In general, imaging should be performed without sedation or general anaesthesia to prevent potentially life-threatening airway compromise, and can be combined with other diagnostic procedures such as surgical biopsy or central line insertion at a later stage if unsafe to perform at presentation.

- **Ultrasound chest** is considered an essential investigation when a CT chest is not possible or where there is suspicion of a large pleural effusion, to further assess the mediastinum for potential tumour and the volume of a pleural effusion which may require emergency tapping prior to transfer or further treatment. If pleural fluid is tapped, it is advisable to collect samples for histology and haematology cytospin. However, the drainage of large volumes of pleural fluid is not advisable due to the risk of expansion oedema and subsequent respiratory collapse.

**Management:**

In a life-threatening situation, children should be managed using an airway, breathing, circulation, disability/neurology approach as per APLS. All cases, especially those with life-threatening mediastinal masses, must be discussed urgently with the attending paediatric consultant.

Children with an anterior mediastinal mass are at risk of sudden and acute respiratory collapse and can deteriorate very rapidly; even if looking clinically well at presentation. The management of these patients is often very difficult and it is therefore vital to have a very low threshold to seek senior support during the initial management period.

Children should be transferred urgently to the tertiary haematology/oncology centre if a mediastinal mass is seen on imaging and/or there is evidence of respiratory distress. Intensive care retrieval to PICU should be considered early.

The specific management of acute lymphoma and leukaemia (the most common causes of a mediastinal mass) is beyond the scope of this article. However, steroids are the emergency treatment of choice for a malignant mediastinal mass, but must not be commenced without careful preparation and discussion with the tertiary centre.
Whilst steroids may be commenced prior to a definitive histological tissue diagnosis in children at significant risk of airway compromise or superior vena cava obstruction, it must be considered that steroids can impair the quality of diagnostic material sampled upon biopsy, with important implications for longer-term treatment, hence a need for discussion with the tertiary centre prior to their prescription. In addition, there is a significant risk of rapid onset tumour lysis following the initiation of steroid treatment, where the rapid destruction of the bulky mass (particularly if T cell malignancy is suspected) can be fatal and requires aggressive prevention and management with intravenous fluid hyper-hydration and concomitant allopurinol or rasburicase (where available). The management of an anterior mediastinal mass where a haematological underlying cause is suspected is summarised in figures 8 and 9 below.

Figure 8 - Management of an anterior mediastinal mass in a child in the paediatric emergency department
Key Management Do’s and Don’t’s:

Figure 9 - Key management ‘dos’ and ‘don’ts’ for a child with suspected or proven anterior mediastinal mass

Take Home Conclusions

- Mediastinal masses are an emergency presentation and can cause life-threatening airway compression.

- Simple investigations with CXR and blood tests may be sufficient to make a preliminary diagnosis at the presenting hospital.

- Staging and further diagnostic work-up, including cross sectional imaging, biopsy of the mass and bone marrow sampling should usually be undertaken in the tertiary centre.

- Steroids are the emergency treatment of choice for children with suspected lymphoma or leukaemia. However, these should only be started after discussion with the tertiary centre and with careful preparation given the high risk of tumour lysis syndrome.

- Some mediastinal masses are truly asymptomatic.

Figure 1 - A clinical case of 'obvious' mediastinal mass seen on chest X-ray presenting to the emergency department.
Figure 2- A clinical case of a 'not-so-obvious' mediastinal mass seen on chest X-ray presenting to the emergency department. Please note that this is not the initial presenting CXR but that taken on arrival at the tertiary oncology centre in PICU.
Key Symptoms of a Mediastinal Mass

- Cough (exacerbated lying flat)
- Chest pain
- Progressive Dyspnoea (especially without history of asthma/inter-current illness)
- Orthopnoea or sleeping with more pillows
- Difficulty Swallowing or choking when eating
- Reduced exercise tolerance (acute exertional breathlessness)
- Symptoms indicating Superior Vena Cava Obstruction- Swelling of the face/head/neck
- Neurological symptoms indicating neurological compromise- headache, dizziness or confusion
- Red flag symptoms of haematological malignancy indicating the cause of mediastinal mass- Bone pain, easy bruising, weight loss
