Summary. Trial-based economic evaluations are typically performed on cross-sectional variables, derived from the responses for only the completers in the study, using methods that ignore the complexities of utility and cost data (e.g. skewness and spikes). We present an alternative and more efficient Bayesian parametric approach to handle missing longitudinal outcomes in economic evaluations, while accounting for the complexities of the data. We specify a flexible parametric model for the observed data and partially identify the distribution of the missing data with partial identifying restrictions and sensitivity parameters. We explore alternative nonignorable scenarios through different priors for the sensitivity parameters, calibrated on the observed data. Our approach is motivated by, and applied to, data from a trial assessing the cost-effectiveness of a new treatment for intellectual disability and challenging behaviour.

1. Introduction

Economic evaluation alongside Randomised Clinical Trials (RCTs) is an important and increasingly popular component of the process of technology appraisal (NICE, 2013). The typical analysis of individual level data involves the comparison of two interventions for which suitable measures of clinical benefits and costs are observed on each patient enrolled in the trial at different time points throughout the follow up.

Typically, clinical benefits are measured through multi-attribute utility instruments (e.g. the EQ-5D-3L: `http://www.euroqol.org`), costs are obtained from clinic resource records and both are summarised into cross-sectional quantities, e.g. Quality Adjusted Life Years (QALYs). The main objective of the economic analysis is a) to combine the population average clinical benefits (or effectiveness) and costs in order to determine the most "cost-effective" intervention, given current evidence; and b) to assess the impact of the uncertainty in the model inputs on the decision-making process (Claxton, 1999;

Briggs, 2000; Spiegelhalter et al., 2004; OHagan et al., 2004; Sculpher et al., 2005; Briggs et al., 2006; Jackson et al., 2009; Baio, 2012).

Individual level data from RCTs are almost invariably affected by missingness. The recorded outcome process is often incomplete due to individuals who drop out or are observed intermittently throughout the study, causing some observations to be missing. In most applications, the economic evaluation is performed on the cross-sectional variables, computed using only the data from the individuals who are observed at each time point in the trial (completers), with at most limited sensitivity analysis to missingness assumptions (Noble et al., 2012; Gabrio et al., 2017; Leurent et al., 2018a). This, however, is an extremely inefficient approach as the information from the responses of all partially observed subjects is completely lost and it is also likely biased unless the completers are a random sample of the subjects on each arm (Little and Rubin, 2002).

When there are missing data, inferences about parameters of interest cannot be obtained without assumptions about the distribution of the missing responses that cannot be verified from the data. When the information from the available data cannot fully explain the systematic differences between observed and unobserved data, missingness can introduce bias in the analysis (Rubin, 1987; Little and Rubin, 2002). Dealing with informative missingness is not straightforward as inference can be drawn only under untestable assumptions about the unobserved data and is often sensitive to the particular assumptions made (Molenberghs et al., 1997). It is therefore desirable to assess the robustness of the inference by varying these assumptions in a principled way (Scharfstein et al., 1999; Vansteelandt et al., 2006; Daniels and Hogan, 2008).

The problem of informative missingness is often embedded within a more complex framework, which makes the modelling task in economic evaluations particularly challenging. Specifically, the effectiveness and cost data typically present a series of complexities that need to be simultaneously addressed to avoid biased results. First, the presence of a bivariate outcome requires the use of appropriate methods that deal with correlation (O'Hagan and Stevens, 2001). Second, repeated utility and cost measurements are typically collected during the trial period for each individual. Under such designs, incomplete data are not unusual, as some of the subjects are not available to be measured at all time points, which presents a considerable modelling challenge for the statistician (Molenberghs et al., 2015). Third, outcome data typically have empirical distributions that are highly skewed. The adoption of parametric distributions that can account for skewness (e.g. Beta for the utilities and Gamma or Log-Normal for the costs) has been suggested to improve the fit (Nixon and Thompson, 2005; Thompson and Nixon, 2005). In addition, data may exhibit spikes at one or both of the boundaries of the range for the underlying distribution that may induce high skewness in the data that is difficult to capture using standard parametric models (Cooper et al., 2003). For example, some patients in a trial may not accrue any cost at all or some individuals may be associated with perfect health, i.e. unit utility. The use of more flexible formulations, known as *hurdle models*, explicitly accounts for these "structural" values. Hurdle models are essentially a mixture between a point mass distribution (the spike) and a parametric model fit to the natural range of the relevant variable without the boundary values. Hurdle models have been applied in economic evaluations for handling either costs or QALYs (Baio, 2014; Gabrio et al., 2019).

To our knowledge, there are no approaches in the literature that are able to jointly handle the complexities of the data in economic evaluations, while also providing a principled approach to explore nonignorable missingness. Alternative approaches have been proposed in the literature to separately handle some of the complexities that affect utility and cost data: correlation and skewness (Gomes et al., 2012), structural values (Basu and Manca, 2012), and missingness under an ignorable assumption (Diaz-Ordaz et al., 2014; Ng et al., 2016). However, these approaches do not simultaneously account for all the complexities of the data and therefore may lead to incorrect results and misleading cost-effectiveness conclusions. Recently, Leurent et al. (2018b) proposed a delta-adjustment method within multiple imputation by chained equations to explore nonignorable missing data assumptions for both outcomes. Despite being simple to implement, this method does not account for the complexities of the data or the time dependence between the responses and does not correspond to a valid probabilistic model.

Using a recent randomised trial as our motivating example, we present a Bayesian parametric model for conducting inference on a bivariate health economic longitudinal response. We specify our model to account for the different types of complexities affecting the data while accommodating a sensitivity analysis to explore the impact of alternative missingness assumptions on the inferences and on the decision-making process for health technology assessment.

1.1. *Positive Behaviour Support Trial*

The Positive Behaviour Support (PBS) study (Hassiotis et al., 2018) is a multicenter randomised controlled trial that, among its objectives, aimed to evaluate the cost-effectiveness of a new multicomponent intervention (PBS, 108 subjects) relative to treatment as usual (TAU, 136 subjects) for individuals suffering from mild to severe intellectual disability and challenging behaviour. The primary instruments used to assess the clinical benefits and costs were the EQ-5D-3L questionnaires and family/paid carer clinic records, respectively. Utilities are derived from the health questionnaires using the time trade-off algorithm (NICE, 2013) and are defined on the interval $[-0.594, 1]$, where 1 represents the perfect health state while negative values indicate states that are considered "worse than death". Costs, expressed in £, are obtained from the clinic records.

Throughout the study, subjects associated with a utility of one, a zero cost or both structural values are observed. Histograms of the empirical distributions of the utilities and costs at each time point in the trial are provided in the Web Appendix. Measurements were scheduled to be collected at baseline and at 6 and 12 months after baseline. By design, the collection of the baseline data in the PBS trial occurred after randomisation and lead to relatively large imbalances in the baseline utilities and costs between the two groups. Since this imbalance may be due, at least partially, to the treatment intervention, baseline variables should also be explicitly modelled to avoid misleading inferences.

Let $\boldsymbol{u}_i = (u_{i0}, \ldots, u_{iJ})$ and $\boldsymbol{c}_i = (c_{i0}, \ldots, c_{iJ})$ denote the vectors of utilities and costs that were supposed to be observed for subject i at time j in the study, with $j \in \{0, 1, J = 2\}$. We denote with $\boldsymbol{y}_{ij} = (u_{ij}, c_{ij})$ the bivariate outcome for subject i formed by the utility and cost pair at time j. Both outcomes were partially observed and missingness was nonmonotone in the sense that if $\boldsymbol{y}_{ij}$ was unobserved then $\boldsymbol{y}_{ij+1}$ could be either observed or unobserved. We group the individuals according to the missingness patterns

and denote with $\boldsymbol{r}_{ij} = (r_{ij}^u, r_{ij}^c)$ a pair of indicator variables that take value 1 if the corresponding outcome for subject i at time j is observed and 0 otherwise. We denote with $\boldsymbol{r}_i = (\boldsymbol{r}_{i0}; \boldsymbol{r}_{i1}; \boldsymbol{r}_{i2})$ the missingness pattern to which subject i belongs, where each pattern is associated with different values for $\boldsymbol{r}_{ij}$. For example, the pattern $\boldsymbol{r} = \boldsymbol{1}$ is associated with the set $\boldsymbol{r} = (1, 1; 1, 1; 1, 1)$ and corresponds to the completers pattern. We denote with R the total number of observed patterns either in the control (9 patterns) or intervention (6 patterns) group. Table 1 reports the missingness patterns in each treatment group as well as the number of individuals and the observed mean responses within each pattern.

<div align="center">TABLE 1 HERE</div>

The number of observed patterns is relatively small and with the exception of the completers ($\boldsymbol{r} = \boldsymbol{1}$) the patterns are quite sparse. Baseline costs in both treatment groups are the only fully observed variables, while the average proportion of missing utilities and costs is respectively 21% and 10% for the control ($v = 1$) and 10% and 8% for the intervention ($v = 2$).

1.2.   Standard Approach to Economic Evaluation

To perform the economic evaluation, aggregated measures for both utilities and costs are typically derived from the longitudinal responses recorded in the study. QALYs (e_{iv}) and total costs (c_{iv}) measures are computed as:

$$e_{iv} = \sum_{j=1}^{J} (u_{ijv} + u_{ij-1v}) \frac{\delta_j}{2} \quad \text{and} \quad c_{iv} = \sum_{j=1}^{J} c_{ijv}, \tag{1}$$

where v denotes the treatment group, while $\delta_j = \frac{\text{Time}_j - \text{Time}_{j-1}}{\text{Unit of time}}$ is the percentage of the time unit (typically one year) which is covered between time $j - 1$ and j in the trial. In the PBS trial, since measurements are collected at 6-month intervals, then $\delta_j = \frac{6 \text{ months}}{12 \text{ months}} = 0.5$ for $j = 1, 2$. Although no individual died in the trial, we note that a utility of 0 is typically associated with a state of death at a given time point, and is carried over until the last follow-up to calculate e_{iv} using Equation 1.

The economic evaluation is then performed by applying some parametric model $p(e_{iv}, c_{iv} \mid \boldsymbol{\theta})$, indexed by a set of parameters $\boldsymbol{\theta}$, to these cross-sectional quantities, typically using linear regression methods to account for the imbalance in some baseline variables between treatments (Manca et al., 2005; Van Asselt et al., 2009; European Medicines Agency, 2013). We note that the term cross-sectional here refers to analyses based on variables derived from the combination of repeated measurements collected at different times over the trial duration and not on data collected at a single point in time. Finally, QALYs and total costs population mean values are derived from the model:

$$\mu_{ev} = \mathrm{E}\left(e_{iv} \mid \boldsymbol{\theta}\right) \quad \text{and} \quad \mu_{cv} = \mathrm{E}\left(c_{iv} \mid \boldsymbol{\theta}\right). \tag{2}$$

The differences in μ_{ev} and μ_{cv} between the treatment groups represent the quantities of interest in the economic evaluation and are used in assessing the relative cost-effectiveness of the interventions.

In the original economic evaluation of the PBS study, the quantities in Equation 1 were derived based on the longitudinal responses for only the completers, while discarding all other partially observed data. Next, the quantities in Equation 2 were obtained under a frequentist approach. The two cross-sectional outcome variables (e_{iv}, c_{iv}) were then modelled independently using normal linear regression methods to control for differences in baseline values, and including the treatment variable to estimate the mean QALYs and cost differentials between groups.

The modelling approach used in the original analysis has the limitation that μ_{ev} and μ_{cv} are derived based only on the completers in the study and does not assess the robustness of the results to a range of plausible missingness assumptions. The model also fails to account for the different complexities that affect the utility and cost data in the trial: from the correlation between variables to the skewness and the presence of structural values (zero for the costs and one for the utilities) in both outcomes.

1.3.   A Longitudinal Model to Deal with Missingness

We propose an alternative approach to deal with a missing bivariate outcome in economic evaluations, while simultaneously allowing for the different complexities that typically affect utility and cost data. Our approach includes a longitudinal model that improves the current practice by taking into account the information from all observed data as well as the time dependence between the responses. The targeted quantities can then be obtained by applying the same formulae in Equation 1 to the marginal means at each time for $\boldsymbol{y}_{ij} = (u_{ij}, c_{ij})$, which can be easily derived from the model. This can be accomplished through the specification of a joint distribution $p(\boldsymbol{y}, \boldsymbol{r} \mid \boldsymbol{\omega})$ for the response and missingness pattern, where $\boldsymbol{\omega}$ is some relevant parameter vector.

We define the data as $\boldsymbol{y} = (\boldsymbol{y}_{obs}, \boldsymbol{y}_{mis})$ to indicate the subsets that are observed and missing. Next, define $p(\boldsymbol{y} \mid \boldsymbol{\theta})$ as the response model, parameterised by $\boldsymbol{\theta}$, and $p(\boldsymbol{r} \mid \boldsymbol{y}, \boldsymbol{\psi})$ as the missingness model, with parameters $\boldsymbol{\psi}$. Missingness is said to be *ignorable* if the following three conditions hold (Little and Rubin, 2002): (1) $p(\boldsymbol{r} \mid \boldsymbol{y}, \boldsymbol{\psi}) = p(\boldsymbol{r} \mid \boldsymbol{y}_{obs}, \boldsymbol{\psi})$, that is, missingness depends only on the observed responses, a condition known as Missing At Random (MAR); (2) the parameter $\boldsymbol{\omega}$ of the joint model $p(\boldsymbol{y}, \boldsymbol{r} \mid \boldsymbol{\omega})$ can be decomposed as $(\boldsymbol{\theta}, \boldsymbol{\psi})$, with $p(\boldsymbol{y} \mid \boldsymbol{\theta})$ and $p(\boldsymbol{r} \mid \boldsymbol{y}, \boldsymbol{\psi})$; (3) the parameters of the response and missingness model are a priori independent, that is $p(\boldsymbol{\omega}) = p(\boldsymbol{\theta})p(\boldsymbol{\psi})$.

When any of these conditions is not satisfied, missingness is said to be *nonignorable*. Often, this is due to the failure of the first condition, which implies $p(\boldsymbol{r} \mid \boldsymbol{y}_{obs}, \boldsymbol{y}_{mis}, \boldsymbol{\psi}) \neq p(\boldsymbol{r} \mid \boldsymbol{y}_{obs}, \boldsymbol{y}'_{mis} \boldsymbol{\psi})$ for $\boldsymbol{y}_{mis} \neq \boldsymbol{y}'_{mis}$, known as Missing Not At Random (MNAR). In this case, the joint model $p(\boldsymbol{y}, \boldsymbol{r})$ will require untestable assumptions about the missing data in order to be identified. We specify our nonignorable modelling strategy using the extrapolation factorisation and a pattern-mixture approach with identifying restrictions (Little, 1994; Linero and Daniels, 2018). The first factors the joint distribution of the response and missingness $p(\boldsymbol{y}, \boldsymbol{r})$ in a way that allows to separate the distribution of $\boldsymbol{y}_{obs}$, for which a flexible parametric model is specified, from the distribution of $\boldsymbol{y}_{mis}$, which is left unidentified. The second specifies the distribution of the responses conditional on the missingness patterns and facilitates the incorporation of external evidence to identify the distribution of $\boldsymbol{y}_{mis}$ and assess the robustness of the results to alternative assumptions.

In this work we present a parametric model with a fully Bayesian framework that can account for both skewness and structural values within a partially-observed outcomes setting. A major advantage of adopting a Bayesian approach is the ability to allow for the formal incorporation of external evidence into the analysis through the use of informative prior distributions. This is a crucial element for conducting sensitivity analysis to assess the robustness of the results to a range of plausible missing data assumptions.

1.4. Outline

In Section 2 we describe the general strategy used to define the model and the factorisation chosen to specify the joint distribution of the cost and utility data and the missingness patterns. In Section 3 we introduce the parametric model implemented for the distribution of the observed data and present alternative specifications to identify the joint model under nonignorability. In Section 4 we introduce the identifying restrictions used and the approach followed to conduct sensitivity analysis. In Section 5 we implement our model to draw inferences on the PBS study under alternative missingness assumptions and summarise the cost-effectiveness results under each scenario from a decision-maker perspective. We close in Section 6 with a discussion.

2. Modelling Framework

We define our modelling strategy following Linero and Daniels (2015) and factor the joint distribution for the response and missingness as:

$$p(\boldsymbol{y}, \boldsymbol{r} \mid \boldsymbol{\omega}) = p(\boldsymbol{y}_{obs}^{r}, \boldsymbol{r} \mid \boldsymbol{\omega}) p(\boldsymbol{y}_{mis}^{r} \mid \boldsymbol{y}_{obs}^{r}, \boldsymbol{r}, \boldsymbol{\omega})$$

where $\boldsymbol{y}_{obs}^{r}$ and $\boldsymbol{y}_{mis}^{r}$ indicate the observed and missing responses within pattern $\boldsymbol{r}$, respectively. This is the extrapolation *factorisation* and factors the joint into two components, of which the extrapolation *distribution* $p(\boldsymbol{y}_{mis}^{r} \mid \boldsymbol{y}_{obs}^{r}, \boldsymbol{r}, \boldsymbol{\omega})$ remains unidentified by the data in the absence of unverifiable assumptions about the full data (Daniels and Hogan, 2008).

To specify the observed data distribution $p(\boldsymbol{y}_{obs}^{r}, \boldsymbol{r} \mid \boldsymbol{\omega})$ we use a working model $p^{\star}$ for the joint distribution of the response and missingness (Linero and Daniels, 2015). Essentially, the idea is to use the working model $p^{\star}(\boldsymbol{y}, \boldsymbol{r} \mid \boldsymbol{\omega})$ to draw inferences about the distribution of the observed data $p(\boldsymbol{y}_{obs}^{r}, \boldsymbol{r} \mid \boldsymbol{\omega})$ by integrating out the missing responses:

$$p(\boldsymbol{y}_{obs}^{r}, \boldsymbol{r} \mid \boldsymbol{\omega}) = \int p^{\star}(\boldsymbol{y}, \boldsymbol{r} \mid \boldsymbol{\omega}) d\boldsymbol{y}_{mis}^{r}.$$

This approach avoids direct specification of the joint distribution of the observed and missing data $p(\boldsymbol{y}, \boldsymbol{r} \mid \boldsymbol{\omega})$, which has the undesirable consequence of identifying the extrapolation distribution with assumptions that are difficult to check. Indeed, since we use $p^{\star}(\boldsymbol{y}, \boldsymbol{r} \mid \boldsymbol{\omega})$ only to obtain a model for $p(\boldsymbol{y}_{obs}^{r}, \boldsymbol{r} \mid \boldsymbol{\omega})$ and not as a basis for inference, the extrapolation distribution is left unidentified. Any inference depending on the observed data distribution may be obtained using the working model as the true model, with the advantage that it is often easier to specify a model for the the full data $p(\boldsymbol{y}, \boldsymbol{r})$ compared with a model for the observed data $p(\boldsymbol{y}_{obs}^{r}, \boldsymbol{r})$.

We specify p^* using a pattern mixture approach, factoring the joint $p(\boldsymbol{y}, \boldsymbol{r} \mid \boldsymbol{\omega})$ as the product between the marginal distribution of the missingness patterns $p(\boldsymbol{r} \mid \boldsymbol{\psi})$ and the distribution of the response conditional on the patterns $p(\boldsymbol{y} \mid \boldsymbol{r}, \boldsymbol{\theta})$, respectively indexed by the distinct parameter vectors $\boldsymbol{\psi}$ and $\boldsymbol{\theta}$. If missingness is monotone it is possible to summarise the patterns by dropout time and directly model the dropout process (Daniels and Hogan, 2008; Gaskins et al., 2016). Unfortunately, as it often occurs in trial-based health economic data, missingness in the PBS study is mostly nonmonotone and the sparsity of the data in most patterns makes it infeasible to fit the response model within each pattern, with the exception of the completers ($\boldsymbol{r} = \boldsymbol{1}$). Thus, we decided to collapse together all the non-completers patterns ($\boldsymbol{r} \neq \boldsymbol{1}$) and fit the model separately to this aggregated pattern and to the completers.

This strategy assumes that reasons for missingness do not largely differ across the non-completers, which may not be realistic in some cases. However, given the paucity of data in the trial, which makes the identification of the model within each pattern not feasible, we believe that the framework offers a reasonable way to identify the distribution of the responses for those who have some unobserved data without relying on the observations from the completers. Alternative nonignorable strategies can be considered to handle sparse data, e.g. parametric selection models, but these are not typically well-suited for conducting sensitivity analysis (Daniels and Hogan, 2008).

The model can be represented as:

$$
\begin{aligned}
p(\boldsymbol{y}, \boldsymbol{r} \mid \boldsymbol{\omega}) = p(\boldsymbol{r} \mid \boldsymbol{\psi}) & \left. [p(\boldsymbol{y} \mid \boldsymbol{r} = \boldsymbol{1}, \boldsymbol{\lambda})]^{\mathbb{I}\{\boldsymbol{r}=\boldsymbol{1}\}} \right\} \\
& \left. \left[\prod_{\boldsymbol{r} \geq 2} p(\boldsymbol{y}_{obs}^{\boldsymbol{r}} \mid \boldsymbol{r}, \boldsymbol{\eta}) \right]^{\mathbb{I}\{\boldsymbol{r} \neq \boldsymbol{1}\}} \right\} \quad \text{observed data distribution} \\
& \left[\prod_{\boldsymbol{r} \geq 2} p\left(\boldsymbol{y}_{mis}^{\boldsymbol{r}} \mid \boldsymbol{y}_{obs}^{\boldsymbol{r}}, \boldsymbol{r}, \boldsymbol{\xi}\right) \right]^{\mathbb{I}\{\boldsymbol{r} \neq \boldsymbol{1}\}} \quad \text{extrapolation distribution}
\end{aligned}
$$

where $\boldsymbol{\omega} = (\boldsymbol{\theta}, \boldsymbol{\psi})$, $\boldsymbol{\lambda}$ and $\boldsymbol{\eta}$ are the distinct subsets of $\boldsymbol{\theta}$ that index the response model in the completers and non-completers patterns, and $\boldsymbol{\xi}$ is the subset of $\boldsymbol{\eta}$ that indexes the extrapolation distribution. The joint distribution has three components. The first is given by the model for the patterns and the model for the completers ($\boldsymbol{r} = \boldsymbol{1}$), where no missingness occurs. The second component is a model for the observed data in the collapsed patterns $\boldsymbol{r} \neq \boldsymbol{1}$ that, together with the first component, form the observed data distribution. The last component is the extrapolation distribution.

Because the targeted quantities of interest (Equation 2) can be derived based on the marginal utility and cost means at each time j, in our analysis we do not require the full identification of $p(\boldsymbol{y}_{mis}^{\boldsymbol{r}} \mid \boldsymbol{y}_{obs}^{\boldsymbol{r}}, \boldsymbol{r}, \boldsymbol{\xi})$. Instead, we only partially identify the extrapolation distribution using *partial identifying restrictions* (Linero and Daniels, 2018). Specifically, we only require the identification of the marginal means for the missing responses in each pattern.

Let $\mathcal{I}^{\boldsymbol{r}}$ be the indices of the missing observations in pattern $\boldsymbol{r}$ and let $\mathcal{J}_{\boldsymbol{r}}^{\boldsymbol{r}'} \subseteq \mathcal{I}^{\boldsymbol{r}}$ be the subset of the indices in $\mathcal{I}^{\boldsymbol{r}}$ for which there are observed responses in $\boldsymbol{r}'$. We denote with $\boldsymbol{y}_{mis}^{\boldsymbol{r}} = \boldsymbol{y}^{\boldsymbol{r}}(\mathcal{I}^{\boldsymbol{r}})$, the missing responses in pattern $\boldsymbol{r}$. Next, we denote with

$\boldsymbol{y}_{obs}^{\boldsymbol{r}'}(\mathcal{J}_{\boldsymbol{r}}^{\boldsymbol{r}'}) \subseteq \boldsymbol{y}_{obs}^{\boldsymbol{r}'}$ the subset of the observed responses in $\boldsymbol{r}'$ that corresponds to $\boldsymbol{y}_{mis}^{\boldsymbol{r}}$. We identify the marginal mean of $\boldsymbol{y}_{mis}^{\boldsymbol{r}}$ using the observed values $\boldsymbol{y}_{obs}^{\boldsymbol{r}'}(\mathcal{J}_{\boldsymbol{r}}^{\boldsymbol{r}'})$, averaged across $\boldsymbol{r}' \neq \boldsymbol{1}$, and some *sensitivity parameters* $\boldsymbol{\Delta} = (\Delta_u, \Delta_c)$. Therefore, we compute the marginal means by averaging only across the observed components in pattern $\boldsymbol{r}'$ and ignore the components that are missing.

$$\mathrm{E}\left[\boldsymbol{y}_{mis}^{\boldsymbol{r}} \mid \boldsymbol{r}\right] = \mathrm{E}\left[\underset{\boldsymbol{r}' \neq \boldsymbol{1}, \mathcal{J}_{\boldsymbol{r}}^{\boldsymbol{r}'}}{\mathrm{E}}\left[\boldsymbol{y}_{obs}^{\boldsymbol{r}'}(\mathcal{J}_{\boldsymbol{r}}^{\boldsymbol{r}'}) + \boldsymbol{\Delta} \mid \boldsymbol{r}'\right]\right]. \tag{3}$$

We start by setting a benchmark assumption with $\boldsymbol{\Delta} = \boldsymbol{0}$, and then explore the sensitivity of the results to alternative scenarios by using different prior distributions on $\boldsymbol{\Delta}$, calibrated on the observed data. We note that $\boldsymbol{\Delta} = \boldsymbol{0}$ does not correspond to a MAR assumption, as with non-monotone patterns, the MAR condition within a nonignorable framework is not transparent and difficult to identify (Molenberghs et al., 2015; Linero and Daniels, 2018). Thus, $\boldsymbol{\Delta} = \boldsymbol{0}$ effectively corresponds to a nonigrnoable analysis with point priors at 0 on all sensitivity parameters. This provides a convenient benchmark scenario from which departures can be explored using alternative informative priors on $\boldsymbol{\Delta}$. Once the working model has been fitted to the observed data and the extrapolation distribution has been identified, the overall marginal mean for the response model can be computed by marginalising over $\boldsymbol{r}$, i.e. $\mathrm{E}\left[\boldsymbol{Y}\right] = \sum_{\boldsymbol{r}} p(\boldsymbol{r})\mathrm{E}\left[\boldsymbol{Y} \mid \boldsymbol{r}\right]$.

3.   Model for the missingness patterns and observed response

Following current practice for modelling missingness in a pattern mixture framework, we specified the distribution of the number of patterns using a multinomial on $\{1, \ldots, R\}$, with the total number of observed patterns R and the probabilities $\boldsymbol{\psi}_v^{\boldsymbol{r}}$, conditional on the treatment assignment v (Daniels and Hogan, 2008; Verbeke and Molenberghs, 2009; Molenberghs et al., 2015; Gaskins et al., 2016). We specify a prior for $\boldsymbol{\psi}_v^{\boldsymbol{r}}$ that gives more weight on the completers pattern and equal weights to the other patterns. Specifically, we choose a Dirichlet$(1 - x, \frac{x}{R^\star}, \ldots, \frac{x}{R^\star})$ prior, where x is the expected total dropout rate and $R^\star = 64$ is the total number of potential patterns in the study. This is consistent with the design of the study, where the experimenter expects at least $(1 - x)\%$ of the individuals to provide complete data, i.e. to fall in $\boldsymbol{r} = \boldsymbol{1}$. In practice, this prior is not likely to affect the results as the amount of observed data is enough to learn the posterior of $\boldsymbol{\psi}_v^{\boldsymbol{r}}$. For comparison purposes, we also consider another specification based on a noninformative Dirichlet$(1, \ldots, 1)$ prior for $\boldsymbol{\psi}_v^{\boldsymbol{r}}$. Posterior results are robust to the alternative prior choices.

The distribution of the observed responses $\boldsymbol{y}_{ijv} = (u_{ijv}, c_{ijv})$ is specified in terms of a model for the utility and cost variables at time $j = 0, 1, 2$, which are jointly modelled without using a multilevel approach and separately by treatment group. In particular, the joint distribution for $\boldsymbol{y}_{ijv}$ is specified as a series of conditional distributions that capture the dependence between utilities and costs as well as the time dependence. We now drop the treatment indicator v for clarity.

Following the recommendations from the published literature, we account for the skewness using Beta and Log-Normal distributions for the utilities and costs, respectively (Basu and Manca, 2012; Ng et al., 2016). Since the Beta distribution does not

allow for negative values, we scaled the utilities on $[0, 1]$ through the transformation $u_{ij}^{\star} = \frac{u_{ij} - \min(\boldsymbol{u}_j)}{\max(\boldsymbol{u}_j) - \min(\boldsymbol{u}_j)}$, and fit the model to these transformed variables. To ease the notation we refer to these quantities simply as u_{ij}.

To account for the structural values $u_{ij} = 1$ and $c_{ij} = 0$ we use a hurdle approach by including in the model the indicator variables $d_{ij}^u := \mathbb{I}(u_{ij} = 1)$ and $d_{ij}^c := \mathbb{I}(c_{ij} = 0)$, which take value 1 if subject i is associated with a structural value at time j and 0 otherwise. The probabilities of observing these values, as well as the mean of each variable, are then modelled conditionally on other variables via linear regressions defined on the logit or log scale. Specifically, at time $j = 1, 2$, the probability of observing a zero and the mean costs are modelled conditionally on the utilities and costs at the previous times, while the probability of observing a one and the mean utilities are modelled conditionally on the current costs (also at $j = 0$) and the utilities at the previous times (only at $j = 1, 2$). The model can be summarised as follows (for simplicity we omit the subject index i).

At time $j = 0$, we model the nonzero costs $c_0 \neq 0$ and the indicator $d_0^c := \mathbb{I}(c_0 = 0)$ as:

$$c_0 \mid d_0^c = 0 \sim \text{LogNormal}\left(\nu_0^c, \tau_0^c\right)$$
$$d_0^c \sim \text{Bernoulli}(\pi_0^c)$$

where ν_0^c and τ_0^c are the mean and standard deviation for c_0 given $c_0 \neq 0$ on the log scale, while π_0^c is the probability of a zero cost value. We next model the utilities and the indicator $d_0^u := \mathbb{I}(u_0 = 1)$ conditionally on the costs at the same time:

$$u_0 \mid d_0^u = 0, c_0 \sim \text{Beta}\left(\nu_0^u, \sigma_0^u\right)$$
$$\text{logit}(\nu_0^u) = \alpha_{00} + \alpha_{10} \log c_0$$
$$d_0^u \mid c_0 \sim \text{Bernoulli}(\pi_0^u)$$
$$\text{logit}(\pi_0^u) = \gamma_{00} + \gamma_{10} \log c_0$$

where ν_0^u and σ_0^u are the mean and standard deviation for u_0 given $u_0 \neq \boldsymbol{1}$ and c_0, while π_0^u is the probability of having a utility value of one given c_0. We parameterise the Beta distributions in terms of mean and standard deviation to facilitate the specification of the priors on the parameters, compared with using the canonical shape parameters (a, b). Specifically, the mean and standard deviation of the Beta distribution are linked to the canonical parameters through the following relationships: $a = \nu\tau$ and $b = (1 - \nu)\tau$, where $\tau = \left(\frac{\nu(1-\nu)}{\sigma^2} - 1\right)$.

We use logistic transformations to define a linear dependence for $p(u_0 \mid c_0, u_0 \neq 1)$ and include the costs on the log scale (after adding a small constant 0.01) to improve the fit of the model. The sensitivity of the results to different values for this constant (from 0.00001 to 0.1) has been assessed and suggest a general robustness of the inferences.

At time $j = 1, 2$, we extend the approach illustrated for $j = 0$, and make a first-order

Markov assumption. For the costs we have:

$$c_j \mid d_j^c = 0, c_{j-1}, u_{j-1} \sim \text{LogNormal}\left(\nu_j^c, \tau_j^c\right)$$
$$\nu_j^c = \beta_{0j} + \beta_{1j} \log c_{j-1} + \beta_{2j} u_{j-1}$$
$$d_j^c \mid c_{j-1}, u_{j-1} \sim \text{Bernoulli}(\pi_j^c)$$
$$\text{logit}(\pi_j^c) = \zeta_{0j} + \zeta_{1j} \log c_{j-1} + \zeta_{2j} u_{j-1}.$$

Similarly to time $j = 0$, the mean, standard deviation and probability parameters for the costs at time j are indicated with ν_j^c, τ_j^c and π_j^c. The regression parameters $\boldsymbol{\beta}_j = (\beta_{0j}, \beta_{1j}, \beta_{2j})$ and $\boldsymbol{\zeta}_j = (\zeta_{0j}, \zeta_{1j}, \zeta_{2j})$ capture the dependence between costs at j and the costs and utilities at $j - 1$, for the non-zero and zero components, respectively. The model for the utilities is:

$$u_j \mid d_j^u = 0, c_j, u_{j-1} \sim \text{Beta}\left(\nu_j^u, \sigma_j^u\right)$$
$$\text{logit}(\nu_j^u) = \alpha_{0j} + \alpha_{1j} \log c_j + \alpha_{2j} u_{j-1}$$
$$d_j^u \mid c_j, u_{j-1} \sim \text{Bernoulli}(\pi_j^u)$$
$$\text{logit}(\pi_j^u) = \gamma_{0j} + \gamma_{1j} \log c_j + \gamma_{2j} u_{j-1}.$$

We denote with ν_j^u, σ_j^u and π_j^u the mean, standard deviation and probability parameters for the utilities at time j, and with $\boldsymbol{\alpha}_j = (\alpha_{0j}, \alpha_{1j}, \alpha_{2j})$ and $\boldsymbol{\gamma}_j = (\gamma_{0j}, \gamma_{1j}, \gamma_{2j})$ the regression parameters that capture the dependence between utilities at j and costs at j and utilities at $j - 1$. Although we believe the proposed Markov assumption provides a reasonable representation of the dependence structure of the data, we acknowledge that alternative specifications could have been used, e.g. costs at time j could depend on the change in utilities $u_j - u_{j-1}$ rather than on the utilities at j.

For all parameters in the model we specify vague prior distributions. Specifically a Normal with a large variance on the appropriate scale for the regression parameters and Uniform over a large positive range for the standard deviations. We implement the model and derive the marginal cost and utility means at each time j through Monte Carlo integration. First, we fit the model separately to the completers ($\boldsymbol{r} = \mathbf{1}$) and the joint set of all other patterns ($\boldsymbol{r} \neq \mathbf{1}$) for $v = 1, 2$. Second, at each iteration of the posterior distribution, we generate a large number of samples for $\boldsymbol{y}_{ij} = (c_{ij}, u_{ij})$ based on the posterior values for the parameters of the utility and cost models in the MCMC output. Third, we approximate the posterior distribution of the marginal means for each $\boldsymbol{r}$ by taking the expectation over these sampled values at each iteration. Finally, we derive the overall marginal means $\boldsymbol{\mu}_{jv} = (\mu_{jv}^c, \mu_{jv}^u)$ as weighted averages across the marginal means in each pattern, using the posterior $\boldsymbol{\psi}_v^{\boldsymbol{r}}$ as weights. We note that, although the model of the observed data distribution requires the specification of a relatively large number of parameters, which may make the model difficult to interpret. However, this does not ultimately affect the final analysis, which exclusively focuses on the marginal means that are retrieved via Monte Carlo integration.

4. Identifying Restrictions and Sensitivity Parameters

As mentioned in Section 2, we use partial identifying restrictions to link the observed data distribution $p(\boldsymbol{y}_{obs}, \boldsymbol{r})$ to the extrapolation distribution $p(\boldsymbol{y}_{mis} \mid \boldsymbol{y}_{obs}, \boldsymbol{r})$ and consider interpretable deviations from a benchmark scenario to assess how inferences are driven by our assumptions (Linero and Daniels, 2018). Specifically, we identify the marginal mean of the missing responses in each pattern $\boldsymbol{y}_{mis}^{\boldsymbol{r}}$ by averaging across the corresponding components that are observed and add the sensitivity parameters $\boldsymbol{\Delta}_j$ (Equation 3).

We define $\boldsymbol{\Delta}_j = (\Delta_{c_j}, \Delta_{u_j})$ to be time-specific location shifts at the marginal mean in each pattern and set $\boldsymbol{\Delta}_j = \boldsymbol{0}$ as the benchmark scenario (Daniels and Hogan, 2000). We then explore departures from this benchmark using alternative priors on $\boldsymbol{\Delta}_j$, which are calibrated using the observed standard deviations for costs and utilities at each time j to define the amplitude of the departures from $\boldsymbol{\Delta}_j = \boldsymbol{0}$ (Section 5.3).

5. Application to the PBS Study

5.1. Computation

We fitted the model using `JAGS`, (Plummer, 2010), a software specifically designed for the analysis of Bayesian models using Markov Chain Monte Carlo (MCMC) simulation (Brooks et al., 2011), which can be interfaced with `R` through the package `R2jags` (Su and Yajima, 2015). Samples from the posterior distribution of the parameters of interest generated by `JAGS` and saved to the `R` workspace are then used to produce summary statistics and plots. We ran two chains with 20,000 iterations per chain, using a burn-in of 5,000, for a total sample of 30,000 iterations for posterior inference. For each unknown quantity in the model, we assessed convergence and autocorrelation of the MCMC simulations using diagnostic measures including the *potential scale reduction factor* and the *effective sample size* (Gelman et al., 2004).

In the non-completers pattern ($\boldsymbol{r} \neq \boldsymbol{1}$), we set to 0 the regression parameters (ζ_{11}, ζ_{21}) and ($\gamma_{10}, \gamma_{11}, \gamma_{21}$) for the model fitted to the control and intervention group, respectively. This simplification was required because, among the non-completers, there is only one observed $c_j = 0$ at time $j = 1$ in the control group and one observed $u_j = 1$ at time $j = \{0, 1\}$ in the intervention group. We therefore drop from the model the dependence between the probabilities of having a structural value at these times and the variables at the previous or same times to ensure the convergence of the algorithm and avoid identifiability problems.

5.2. Model Assessment

We computed the Deviance Information Criterion (DIC; Spiegelhalter et al., 2002) to assess the fit of the model with respect to an alternative parametric specification, where the LogNormal distributions are replaced with Gamma distributions for the cost variables. The DIC is a measure of comparative predictive ability based on the model deviance and a penalty for model complexity known as effective number of parameters (p_D). When comparing a set of models based on the same data, the one associated with the lowest DIC is the best-performing, among those assessed. There are different ways of constructing the DIC in the presence of missing data, which means that its use and interpretation

are not straightforward (Celeux et al., 2006; Daniels and Hogan, 2008; Mason et al., 2012). In our analysis, we consider a DIC based on the observed data under MAR as its value does not depend on the values of the sensitivity parameters (Wang and Daniels, 2011). Because the sampling distribution of the observed data was not available in closed form, we computed it using Monte Carlo integration. Results between the two alternative specifications are reported in Table 2.

<div align="center">TABLE 2 HERE</div>

The DIC components for the costs are systematically lower when LogNormal distributions are used compared with Gamma distributions (lower values shown in italics in Table 2), and result in an overall better fit to the data for the first model.

We also assess the absolute fit of the model using posterior predictive checks based on observed data replications (Xu et al., 2016). We sample from the posterior predictive distribution $p(\tilde{\boldsymbol{y}}, \tilde{\boldsymbol{r}} \mid \boldsymbol{y}_{obs}^r, \boldsymbol{r}, \boldsymbol{\omega})$. Conditional on the replicated patterns $\tilde{\boldsymbol{r}}$, we define the replicated observed data in each pattern as $\tilde{\boldsymbol{y}}_{obs}^{\tilde{\boldsymbol{r}}} = \{\tilde{\boldsymbol{y}}_j : \tilde{\boldsymbol{r}}_j = \boldsymbol{1}\}$, that is the components of $\tilde{\boldsymbol{y}}$ for which the corresponding missing data indicators at time j in the replicated patterns $\tilde{\boldsymbol{r}}$ are equal to one.

We compute the rank correlations between each pair of variables for each replicated dataset, and compare them with the corresponding values from the real dataset. The results, shown in Figure 1, suggest that the proposed parametric model captures most of the correlations well both in the control (panel a) and intervention (panel b) group.

<div align="center">FIGURE 1 HERE</div>

5.3. Priors on Sensitivity Parameters

We consider three alternative sets of priors on $\boldsymbol{\Delta}_j = (\Delta_{u_j}, \Delta_{c_j})$, calibrated based on the variability in the observed data at each time j. The three types of priors used are the following:

- L-$\boldsymbol{\Delta}^{\text{flat}}$: Flat between 0 and twice the observed standard deviation:

$$\Delta_{c_j} \sim \text{Uniform}[0, 2\,\text{sd}(c_j)] \quad \text{and} \quad \Delta_{u_j} \sim \text{Uniform}[-2\,\text{sd}(u_j), 0]$$

- L-$\boldsymbol{\Delta}^{\text{skew0}}$: Skewed towards values closer to 0, over the same range as L-$\boldsymbol{\Delta}^{\text{flat}}$:

$$\Delta_{c_j} = 2\,\text{sd}(c_j)\left(1 - \sqrt{U}\right) \quad \text{and} \quad \Delta_{u_j} = -2\,\text{sd}(u_j)\left(1 - \sqrt{U}\right)$$

- L-$\boldsymbol{\Delta}^{\text{skew1}}$: Skewed towards values far from 0, over the same range as L-$\boldsymbol{\Delta}^{\text{flat}}$:

$$\Delta_{c_j} = 2\,\text{sd}(c_j)\left(\sqrt{U}\right) \quad \text{and} \quad \Delta_{u_j} = -2\,\text{sd}(u_j)\left(\sqrt{U}\right),$$

where $U \sim \text{Uniform}(0, 1)$ and $\text{sd}(u_j)$ and $\text{sd}(c_j)$ are the standard deviations computed on the observed utilities and costs at time j for the non-completers ($\boldsymbol{r} \neq \boldsymbol{1}$). We choose these priors because we believe that departures from L-$\boldsymbol{\Delta} = 0$ for both outcomes are not likely to be larger than twice the observed standard deviations at each time j. A graphical representation of the densities associated with the three alternative priors used is provided in the Web Appendix.

5.4. Results

This section summarises and discusses the results from the posterior distribution of the main quantities of interest in the model, namely the marginal mean utility and cost parameters at each time point $\boldsymbol{\mu}_{jv}$ and the marginal mean QALYs and total costs (μ_{ev}, μ_{cv}) evaluated over the trial duration.

Figure 2 compares the posterior means and 95% highest posterior density (HPD) credible intervals for $\boldsymbol{\mu}_{jv} = (\mu_{jv}^u, \mu_{jv}^c)$ obtained from fitting the model under six alternative scenarios: completers (L-CC), all cases assuming ignorability (L-MAR), and using the extrapolation factorisation under the benchmark (L-$\boldsymbol{\Delta}_j = \boldsymbol{0}$) and three departure scenarios (L-$\boldsymbol{\Delta}^{\text{flat}}$,L-$\boldsymbol{\Delta}^{\text{skew0}}$,L-$\boldsymbol{\Delta}^{\text{skew1}}$). Since baseline costs are fully observed, only the estimates under L-CC and L-MAR are shown for $\boldsymbol{\mu}_0^c$. Results associated with the control and intervention group are indicated in light and dark colours, respectively.

FIGURE 2 HERE

The distributions of both $\boldsymbol{\mu}_j^u$ and $\boldsymbol{\mu}_j^c$ show values that are higher in the intervention compared with the control at each time j, and show relatively similar mean estimates across L-CC, L-MAR and L-$\boldsymbol{\Delta} = \boldsymbol{0}$. However, under the other nonignorable scenarios, mean utilities/costs are on average 3% (L-$\boldsymbol{\Delta}^{\text{flat}}$), 4% (L-$\boldsymbol{\Delta}^{\text{skew0}}$) and 5% (L-$\boldsymbol{\Delta}^{\text{skew1}}$) lower/higher compared with L-$\boldsymbol{\Delta} = \boldsymbol{0}$ in the control group. In the intervention group, mean utilities/costs are on average 1% (L-$\boldsymbol{\Delta}^{\text{flat}}$), 1.5% (L-$\boldsymbol{\Delta}^{\text{skew0}}$) and 2.5% (L-$\boldsymbol{\Delta}^{\text{skew1}}$) lower/higher compared with $\boldsymbol{\Delta} = \boldsymbol{0}$. In spite of the variations between the mean estimates, overall, the HPD intervals for each marginal mean utility and cost parameter do not show edivence of large discrepancies across all scenarios.

We then derived the QALYs and total costs means μ_{ev} and μ_{cv} by applying the formulae in Equation 1 to the cost and utility marginal means $\boldsymbol{\mu}_{jv}$ obtained from the model. We also compare the estimates derived from our approach with those obtained from two cross-sectional models fitted on e_i and c_i, computed only based on the completers in the study. The first, denoted with CS-IND, specified following the approach used in the original analysis of the PBS study (assuming independent normal distributions for the two outcomes and including baseline adjustments), but implemented within a Bayesian framework. The second, denoted wth CS-HUR, is specified using a Beta-LogNormal distribution with a hurdle approach to handle both unit QALYs and zero total costs.

Table 3 shows the posterior means and 95% HPD credible intervals associated with the targeted quantities under all scenarios for both treatment groups.

TABLE 3

The estimates under the two cross-sectional models (CS-IND and CS-HUR) are relatively close to those derived from the longitudinal model fitted only to the completers (L-CC). These estimates are generally higher with respect to those from the model that additionally incorporates the evidence from the non-completers (L-MAR), both for the QALYs and total costs. The estimates under the non-ignorable scenarios are systematically lower for mean QALYs and are systematically higher for mean total costs compared with the other scenarios in both treatment groups, although the HPD intervals for μ_{ev} and μ_{cv} show a considerable overlap across all scenarios. These variations are larger in the control, which has higher proportions of non-completers with respect to the intervention.

5.5. Economic Evaluation

We complete the analysis by assessing the cost-effectiveness of the new intervention with respect to the control, comparing the results under the cross-sectional (CS-IND), complete case (L-CC), ignorable (L-MAR), benchmark nonignorable (L-$\Delta = \mathbf{0}$) and the three alternative nonignorable departure scenarios. We specifically rely on the examination of the Cost-Effectiveness Plane (CEP; Black, 1990) and the Cost-Effectiveness Acceptability Curve (CEAC; Van Hout et al., 1994) to summarise the economic analysis.

FIGURE 3 HERE

The CEP (Figure 3, panel a) is a graphical representation of the joint distribution for the population average effectiveness and costs increments between the two arms, indicated respectively as $\mu_{e2} - \mu_{e1}$ and $\mu_{c2} - \mu_{c1}$. Each dot in the plane corresponds to the value of the parameters drawn from the posterior distributions of the expected mean QALYs and total costs, evaluated at each iteration of the MCMC output.

We show the results only under three scenarios (indicated with lighter to darker colours for L-CC, L-MAR and L-Δ^{flat}, respectively) for clarity and visualisation purposes. The results for the other nonignorable scenarios are available in the Web Appendix. The slope of the straight line crossing the plane is the "willingness to pay" threshold (often indicated as k). Following current recommendations for trial-based economic analyses, we choose a willingness to pay threshold of £25,000 per QALY gained (NICE, 2013). This can be considered as the amount of budget the decision-maker is willing to spend to increase the health outcome of one unit and effectively is used to trade clinical benefits for money. Points lying below this straight line fall in the so-called *sustainability area* (Baio, 2012) and suggest that the active intervention is more cost-effective than the control. In the graph, we also show the Incremental Cost-Effectiveness Ratio (ICER) computed under each scenario, as darker coloured dots. This is defined as

$$\text{ICER} = \frac{\text{E}[\mu_{c2} - \mu_{c1}]}{\text{E}[\mu_{e2} - \mu_{e1}]}$$

and quantifies the cost per incremental unit of effectiveness.

For all three scenarios almost all samples fall in the North-East quadrant and their ICERs fall in the sustainability area. This suggests that under all scenarios the intervention is likely to be cost-effective by producing both QALY gains and cost savings compared with the control. However, the ICERs associated with L-CC and L-MAR are only slightly lower than the threshold value of $k = £25,000$ and are therefore associated with more uncertain cost-effectiveness decisions compared with L-Δ^{flat}. This is also indicated by the full distribution of the CEP which is shifted to the right under L-Δ^{flat} with respect to the other two scenarios (therefore suggesting a more favourable conclusion for the intervention).

The CEAC (Figure 3, panel b) is obtained by computing the proportion of points lying in the sustainability area upon varying the willingness to pay threshold k. Based on standard practice in routine analyses, we consider a range for k up to £40,000 per QALY gained. The CEAC estimates the probability of cost-effectiveness, thus providing a simple summary of the uncertainty associated with the "optimal" decision-making suggested by the ICER. The results under L-CC and L-MAR are reported using solid

curves. In addition, the results derived under nonignorability are reported using different dashed lines.

The CEACs under L-CC, L-MAR and the benchmark scenarios show a similar trend and indicate a probability of cost-effectiveness below 0.65 of the new intervention for values of k up to £40,000. However, under the other scenarios, the curve is shifted upwards by an average probability of 0.2 (L-$\mathbf{\Delta}^{\text{flat}}$), 0.15 (L-$\mathbf{\Delta}^{\text{skew0}}$) and 0.25 (L-$\mathbf{\Delta}^{\text{skew1}}$) and suggests a more favourable cost-effectiveness assessment.

We finally compare the economic results under our longitudinal approach with respect to those derived from the two cross-sectional models CS-IND and CS-HUR. Figure 4 shows the CEPs (panel a) associated with the CS-IND, CS-HUR and L-CC scenarios, respectively indicated with darker to lighter coloured dots. In the CEACs (panel b), in addition to the probability values associated with these scenarios, the results from $L - MAR$ and L-$\mathbf{\Delta}^{\text{flat}}$ are indicated using dashed and solid lines for the cross-sectional and longitudinal models, respectively.

FIGURE 4 HERE

The distribution of the posterior samples in the CEP (Figure 4, panel a) show relatively small differences between the scenarios, with the ICER of CS-IND being the lowest among those compared. In the CEAC (Figure 4, panel b), the acceptability curve for CS-IND is generally higher than those for CS-HUR, L-CC and L-MAR for most willingness to pay values but remains systematically lower with respect to L-$\mathbf{\Delta}^{\text{flat}}$, L-$\mathbf{\Delta}^{\text{skew0}}$ and L-$\mathbf{\Delta}^{\text{skew1}}$ (in Figure 4 we only show the results for L-$\mathbf{\Delta}^{\text{flat}}$ for clarity).

Overall, both inferences and cost-effectiveness conclusions are sensitive to the assumptions about the missing values, which can lead to a considerable change in the output of the decision process and the cost-effectiveness conclusions. More specifically, the results from L-CC are relatively close to those from the cross-sectional analyses (CS-IND and CS-HUR). When the information from all observed cases is incorporated into the model (L-MAR and L-$\mathbf{\Delta} = \mathbf{0}$), the results suggest a more cost-effective intervention, although the magnitude of this change is relatively small. Finally, under the three non-ignorable scenarios assessed (L-$\mathbf{\Delta}^{\text{flat}}$, L-$\mathbf{\Delta}^{\text{skew0}}$ and L-$\mathbf{\Delta}^{\text{skew1}}$), a considerably more favourable economic assessment for the new intervention is obtained.

We note that the results from these analyses should be interpreted with caution. Indeed, by construction, CEACs are only concerned with currently available information and do not consider explicitly the possibility of gathering additional evidence, therefore providing only a partial evaluation of the overall decision process (Koerkamp et al., 2007). Despite their limitations, however, CEACs represent the standard tools used by practitioners in trial-based analyses to report the economic results, particularly for small trials, where the objective is to provide a preliminary assessment of cost-effectiveness. Since all analyses in this article are based on a trial, we follow current practice and use CEACs as the main tool to summarise the uncertainty about the cost-effectiveness of the intervention (NICE, 2013; Ramsey et al., 2015).

6. Discussion

Missingness represents a threat to economic evaluations as, when dealing with partially-observed data, any analysis makes assumptions about the missing values that cannot be

verified from the data at hand. Trial-based analyses are typically conducted on cross-sectional quantities, e.g. QALYs and total costs, which are derived based only on the observed data from the completers in the study. This is an inefficient approach which may discard a substantial proportion of the sample, especially when there is a relatively large number of time points, where individuals are more likely to have some missing value or to drop out from the study. In addition, when there are systematic differences between the responses of the completers and non-completers, which is typically the case when dealing with self-reported outcomes in trial-based analyses, the results based only on the former may be biased and mislead the final assessment. A further concern is that routine analyses typically rely on standard models that ignore or at best fail to properly account for potentially important features in the data such as correlation, skewness, and the presence of structural values.

In this paper, we have proposed an alternative approach for conducting parametric Bayesian inference under nonignorable missingness for a longitudinal bivariate outcome in health economic evaluations, while accounting for typical data features such as skewness and presence of structural values in both utilities and costs. The analysis of the PBS data shows the benefits of using our approach compared with a standard cross-sectional model and a considerable impact of alternative MNAR assumptions on the final decision-making conclusions, suggesting a more cost-effective intervention compared with the results obtained under ignorability (L-MAR).

There are two main potential limitations of the proposed framework. First, the choice of aggregating all non-completers into a single pattern to handle the sparsity of the data is relatively simple to implement but rests on the critical assumption that reasons for missingness should not largely differ across these patterns, which, however, may not be realistic in more general situations. Second, the model may become computationally challenging to implement when the number of variables (i.e. time points) increases. Alternative approaches could be used to overcome these limitations. For example, the sparsity of the data in certain missingness patterns could be handled by specifying shared prior distributions across the patterns to identify the parameters in each pattern by sharing the information from the observed data across all or some of the patterns (Gaskins et al., 2016). A full Baysian non-parametric specification could also be used to handle sparse data (Linero and Daniels, 2015).

Gomes et al. (2019) have recently proposed a nonignorable approach for bivariate outcomes which combines multiple imputation methods with a copula selection model to allow for non-Normal outcomes while simultaneously imputing missing outcome data under MNAR. However, this approach relies on parametric assumptions about the joint distribution of the observed and missing data, which are typically difficult to check and do not allow us to introduce sensitivity parameters (Daniels and Hogan, 2008). By contrast, our approach is based on the extrapolation factorisation which allows a flexible specification of the model for the observed data. The extrapolation distribution is then separately identified only up to the marginal mean with partial identifying restrictions using the marginal means estimated from the non-completers. As an alternative approach, we could have used the marginal mean estimates from the completers, but we considered those of the incompleters as a more reasonable default MNAR assumption. Next, we used sensitivity parameters to characterise the uncertainty about the missing data

within each pattern. Our framework may be particularly useful when external sources of information about missingness are available (e.g. expert opinion) as they can be formally incorporated into the model and their impact on the results can be transparently assessed using different priors on the sensitivity parameters.

Although the priors for the sensitivity parameters in Section 5.3 were not derived from a formal elicitation of expert opinion, given that it was not available in the PBS study, they offer a convenient framework to assess the robustness of the conclusions to differing MNAR departures based on the magnitude of quantities (e.g. the variance) from the observed data. In our analysis we only considered departures where missing values were assumed to be associated with higher utilities and lower costs compared with the observed data at each time point (exploring different variations). We choose these departures based on a discussion with the people involved in the trial and to provide a reasonable number of scenarios to explore. However, in general cases these assumptions may not be plausible and alternative departures could be considered based on the available information about missingness.

Our framework represents a considerable step forward for the handling of missingness in economic evaluations compared with the current practice, which typically relies on methods that assume an ignorable MAR and rarely conducts sensitivity analysis to MNAR departures. Nevertheless, further improvements are certainly possible. For example, a potential area for future work is to increase the flexibility of our approach through a semi-parametric or nonparametric specification for the observed data distribution, which would allow a weakening of the model assumptions and likely further improve the fit of the model to the observed data and address sparse patterns in an automated way. As for the extrapolation distribution, alternative identifying restrictions that introduce the sensitivity parameters via the conditional mean (rather than the marginal mean) could be considered, and their impact on the conclusions assessed in a sensitivity analysis.

Table 1. Missingness patterns for the outcome $y_j = (u_j, c_j)$ in the PBS study. For each pattern and treatment group, the number of subjects (n_{rt}) and the observed mean responses at each time $j = 0, 1, 2$ are reported. We denote the absence of response values or individuals within each pattern with −.
		control ($v=1$)							intervention ($v=2$)

$u_2 \mid u_1, c_2$	-454.07	5.87	-453.47	5.99
Total	4667	25	*4518*	25
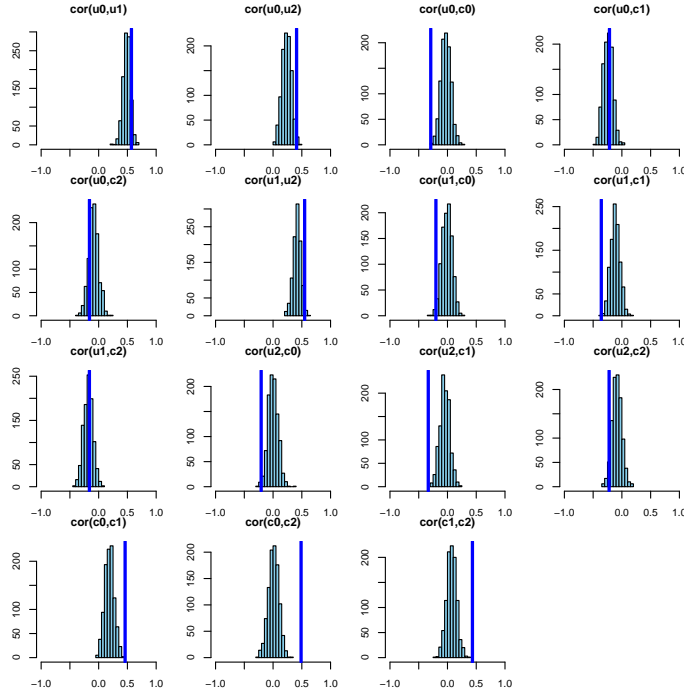

(a) control

(b) intervention

Fig. 1. Posterior predictive distributions for the pairwise correlation between utilities and costs variables in the control (panel a) and intervention (panel b) arm across 1000 observed replicated datasets (light blue bars) compared with the estimates based on the observed data in the real dataset (vertical blue lines).
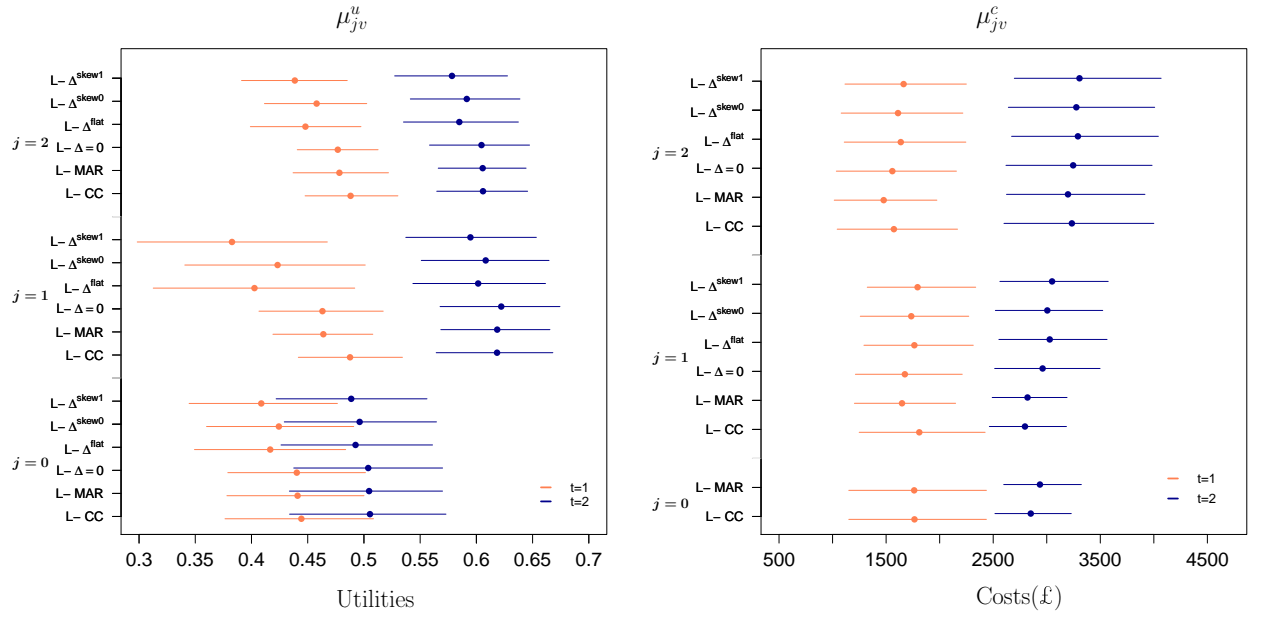

Fig. 2. Posterior means and 95% HPD intervals for the marginal utility and cost means in the control (red dots and lines) and intervention (blue dots and lines) group at each time j in the study across alternative assumptions. Six scenarios are compared: completers (L-CC), ignorability (L-MAR), and nonignorability using the extrapolation factorisation under the benchmark assumption (L-$\Delta = 0$) and under the three scenarios described in Section 5.3 (L-Δ^{flat}, L-Δ^{skew0}, L-Δ^{skew1}). Since the baseline costs are fully observed in both groups, only the results under l-L-CC and L-MAR are displayed for $\boldsymbol{\mu}_0^c$.

Table 3. Posterior means and 95% HPD credible intervals for μ_{et} and μ_{ct} in the control ($v = 1$) and intervention ($v = 2$) group under alternative scenarios: Cross-Sectional (CS-IND and CS-HUR), L-CC, L-MAR, L-$\mathbf{\Delta} = \mathbf{0}$, L-$\mathbf{\Delta}^{\text{flat}}$, L-$\mathbf{\Delta}^{\text{skew0}}$ and L-$\mathbf{\Delta}^{\text{skew1}}$

| Scenario	μ_{e1}		μ_{e2}		μ_{c1}		μ_{c2}	
	mean	95% CI	mean	95% CI	mean	95% CI	mean	95% CI
CS-IND	0.49	(0.45; 0.52)	0.61	(0.57; 0.65)	3073	(2188; 3915)	5768	(5115; 6413)
CS-HUR	0.49	(0.46; 0.52)	0.60	(0.56; 0.63)	3283	(2459; 4261)	5919	(5385; 6506)
L-CC	0.48	(0.45; 0.51)	0.59	(0.55; 0.62)	3382	(2583; 4246)	6031	(5281; 6889)
L-MAR	0.46	(0.43; 0.49)	0.59	(0.56; 0.62)	3125	(2483; 3846)	6018	(5314; 6806)
L-$\mathbf{\Delta} = \mathbf{0}$	0.46	(0.42; 0.49)	0.59	(0.56; 0.62)	3233	(2489; 4041)	6208	(5364; 7142)
L-$\mathbf{\Delta}^{\text{flat}}$	0.42	(0.36; 0.47)	0.57	(0.53; 0.61)	3400	(2616; 4196)	6318	(5462; 7271)
L-$\mathbf{\Delta}^{\text{skew0}}$	0.43	(0.39; 0.48)	0.58	(0.54; 0.61)	3345	(2605; 4173)	6281	(5409; 7200)
L-$\mathbf{\Delta}^{\text{skew1}}$	0.40	(0.35; 0.45)	0.56	(0.53; 0.60)	3457	(2678; 4250)	6355	(5522; 7332)
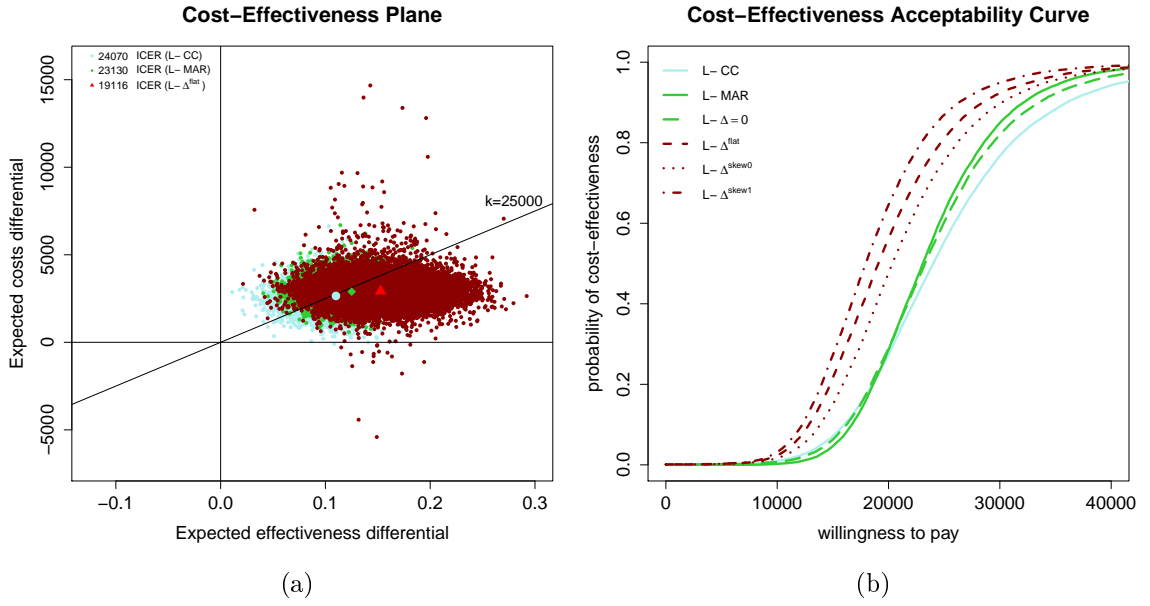

Fig. 3. CEPs (panel a) and CEACs (panel b) associated with alternative missingness scenarios. In the CEPs, the Incremental-Cost-Effectiveness Ratios based on the results from L-CC, L-MAR and L-Δ^{flat} are indicated with corresponding darker coloured dots, while the portion of the plane on the right-hand side of the straight line passing through the plot (evaluated at $k = £25,000$) denotes the sustainability area. For the CEACs, in addition to the results under L-CC and L-MAR (solid lines), the probability values for the alternative scenarios are represented with different coloured dashed lines.
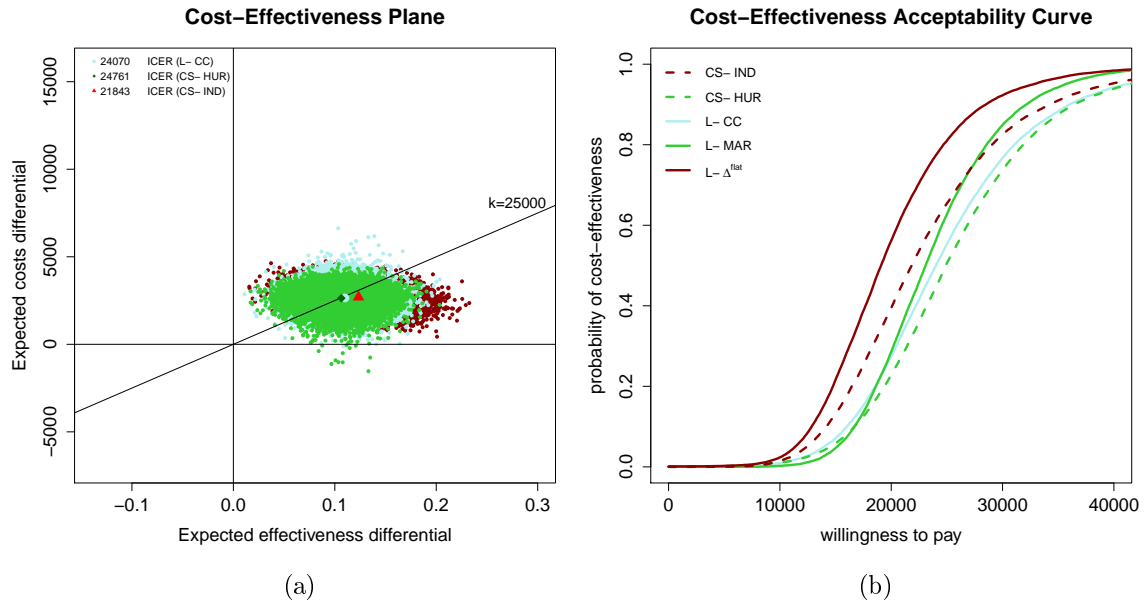

Cost–Effectiveness Plane

Cost–Effectiveness Acceptability Curve
