We present the results of a direct detection search for mirror dark matter interactions, using data collected from the Large Underground Xenon experiment during 2013, with an exposure of 95 live-days × 118 kg. Here, the calculations of the mirror electron scattering rate in liquid xenon take into account the shielding effects from mirror dark matter captured within the Earth. Annual and diurnal modulation of the dark matter flux and atomic shell effects in xenon are also accounted for. Having found no evidence for an electron recoil signal induced by mirror dark matter interactions we place an upper limit on the kinetic mixing parameter over a range of local mirror electron temperatures between 0.1 and 0.9 keV. This limit shows significant improvement over the previous experimental constraint from orthopositronium decays and significantly reduces the allowed parameter space for the model. We exclude mirror electron temperatures above 0.3 keV at a 90% confidence level, for this model, and constrain the kinetic mixing below this temperature.

DOI: 10.1103/PhysRevD.101.012003

I. INTRODUCTION

The Standard Model (SM) is a gauge field theory with SU(3)C ⊗ SU(2)L ⊗ U(1)Y gauge symmetry. It successfully describes known particles and their nongravitational interactions, but does not contain a suitable dark matter candidate. One possibility for accommodating dark matter particles is that they exist in a hidden sector—a collection of particles and fields which do not interact via SM gauge boson forces, but do interact with SM particles gravitationally [1]. Mirror dark matter is a special case where the hidden sector is exactly isomorphic to the SM [2], having the same gauge symmetry. Therefore, it contains mirror partners (denoted ‘*) of the SM particles with the same masses, lifetimes, and self-interactions. The full Lagrangian may be written as

$$\mathcal{L} = \mathcal{L}_{\text{SM}}(e, u, d, \gamma, W, Z, \ldots) + \mathcal{L}_{\text{SM}}'(e', u', d', \gamma', W', Z', \ldots) + \mathcal{L}_{\text{mix}}.$$  (1)

where $\mathcal{L}_{\text{SM}}(e, \ldots)$ and $\mathcal{L}_{\text{SM}}'(e', \ldots)$ are the Lagrangians for the SM and mirror sectors, respectively. The two sectors are related by a discrete $Z_2$ symmetry transformation, with the only allowed nongravitational interactions given by

$$\mathcal{L}_{\text{mix}} = \frac{\epsilon}{2} F_{\mu\nu} F^{\mu\nu} + \lambda \phi^\dagger \phi \phi^\dagger \phi'.$$  (2)

Here, the first term describes kinetic mixing of $U(1)_Y$ and mirror $U(1)'_Y$, with field strength tensors $F_{\mu\nu}$, $F'_{\mu\nu}$ and kinetic mixing strength $\epsilon$ [3]. The second term describes Higgs ($\phi$)-mirror Higgs ($\phi'$) mixing, with strength determined by parameter $\lambda$. Kinetic mixing induces tiny ordinary electric charges, $\pm \epsilon e e$ for the mirror protons and electrons [4]. This allows very weak electromagnetic interactions between mirror and SM particles. The kinetic mixing parameter, $\epsilon$, determines the strength of most mirror—SM particle couplings and is thus the target of experimental searches. The Higgs-mirror Higgs portal can be probed at colliders, through Higgs production and decays, but does not give observable signals in direct detection experiments [2].

Within the mirror dark matter model, kinetic mixing is constrained theoretically to lie in the range $10^{-11} \leq \epsilon \leq 4 \times 10^{-10}$ [2]. In order for the mirror dark matter halo to be in equilibrium, heating from supernovae must balance energy loss from dissipative processes, giving the lower limit on $\epsilon$ [5]. But if $\epsilon$ is too high, cosmic structure formation would be too heavily damped, giving the upper limit [6].

II. LUX EXPERIMENT

The Large Underground Xenon (LUX) experiment was a dual phase (liquid-gas) time projection chamber (TPC), containing a 250 kg active mass of liquid xenon. The main aim of LUX was to search for dark matter in the form of weakly interacting massive particles (WIMPs), placing limits on spin-independent WIMP-nucleon cross sections for WIMP masses above 4 GeV [7,8]. Other studies include...
searches for spin-dependent WIMP-nucleon interactions [9], electron recoil searches for solar axions and axionlike particles [10], and sub-GeV dark matter via the bremsstrahlung and Migdal effects [11].

As described in Ref. [12], the LUX TPC was located in a low-radioactivity titanium cryostat, itself within a 6.1 m high, 7.6 m diameter water tank 1458 m underground at the Sanford Underground Research Facility, Lead, USA. Details of the detector calibration and performance are available in Ref. [13]. When a particle interacts in the liquid xenon, prompt scintillation photons (S1) and ionization electrons are produced. The ionization electrons are drifted upward by a vertical electric field and extracted into the gas phase, where they produce an electroluminescence signal (S2). Photons from these signals are detected by two arrays of 61 photomultiplier tubes, above and below the active volume. The (x,y) position is obtained from the S2 light pattern for this process is given by [15]

$$\frac{d\sigma}{dE_R} = \frac{\lambda}{E_R^2 E^2}, \quad \lambda = \frac{2\pi e^2 \alpha^2}{m_e}. \quad (4)$$

Here $E_R$ is electron recoil energy, $v$ velocity of the incoming mirror electron, $m_e$ electron mass, $\epsilon$ the kinetic mixing parameter, and $\alpha$ the fine structure constant. The scattering rate, calculated by multiplying with the integral of the velocity distribution of the incoming mirror dark matter and Taylor expanding around the yearly average, is given by [17]

$$\frac{dR}{dE_R} = g_T N_T n^0_v \frac{\lambda}{v^2_R E_R^2} [1 + A_v \cos \omega(t - t_0) + A_\theta (\theta - \bar{\theta})]. \quad (5)$$

Here $N_T$ is the number of target electrons, $n^0_v$ the number density of mirror electrons arriving at the detector, and $v^0_R$ describes the modified velocity distribution at the detector due to shielding. The effective number of free electrons, $g_T$, is the number of electrons per target atom with atomic binding energy ($E_b$) less than recoil energy ($E_R$)—modeled as a step function for the atomic shells in xenon.

The $A_v \cos \omega(t - t_0)$ term describes annual modulation resulting from the change of velocity of the Earth with respect to the dark matter halo. Here $\omega = 2\pi / year$, $t_0 = 153$ days (June 2) and modulation amplitude $A_v = 0.7$ [17]. The $A_\theta (\theta - \bar{\theta})$ term describes diurnal and annual modulation due to the rotation of the Earth and the variation of the Earth’s spin axis relative to the incoming dark matter wind. Here $\theta$ is the angle between the halo wind and the zenith at the detector location, $\bar{\theta}$ is the yearly average, and the amplitude is $A_\theta = 1$. The time variation of $\theta$ is examined in [15]. The mean modulation terms over the data taking period, accounting for the live time per day, are $A_v (\cos \omega(t - t_0)) = 0.556$ and $A_\theta (\theta - \bar{\theta}) = 0.015$.

Equation (4) shows that $d\sigma / dE_R \propto 1 / v^2$, so the collision length $\propto v^2$. This means that for sufficiently large incoming
velocity, the effect of collisions becomes negligible (as scattering length exceeds the available distance). Therefore, above some cutoff velocity, \( v_{\text{cut}} \), collisions do not need to be considered. Below this velocity collisions are important until mirror electron energy is reduced to \( ~25 \text{ eV} \), after which energy loss to the captured mirror helium is no longer important. From energy loss considerations, the cutoff velocity may be estimated as [17]

\[
v_{\text{cut}}^4 \approx \frac{16\pi}{m_e^2} \alpha^2 \log \Lambda,
\]

where \( \Lambda \approx T/E_{\text{min}} \approx 20 \), with minimum collisional energy loss \( E_{\text{min}} \). Column density, \( \Sigma \), is calculated by integrating the number density of captured mirror helium nuclei over the path of the incoming mirror dark matter particle,

\[
\Sigma(\psi) = \int n_{\text{He}} \, dl.
\]

Here \( \psi \) is the angle between the direction of the incoming mirror electron and the zenith at the detectors location and \( l \) is the distance traveled.

The energy dependent term describing the velocity distribution is given by [17]

\[
\frac{1}{v_0^4} = \frac{1}{Nv_0} \int e^{-\psi/v_0^2} d\psi d\cos \psi,
\]

where \( v_0 = \sqrt{2T/m_e} \) is the velocity dispersion. Dependence on recoil energy is through \( \gamma = \text{MAX}[v_{\text{cut}}(\psi), v_{\text{min}}(E_R)] \), where \( v_{\text{min}}(E_R) = \sqrt{2E_R/m_e} \) is the minimum velocity needed to produce a recoil of energy \( E_R \).

The dependence of \( v_0^4 \) on recoil energy is shown in Fig. 1. At low values of \( E_R \) the average velocity exceeds the minimum, \( |v| \gg v_{\text{min}} \), so most particles can produce recoils with energy \( E_R \) and the integral becomes independent of \( v_{\text{min}} \). For large \( E_R \), the average particle velocity is lower than \( v_{\text{min}} \), so the integral is suppressed, leading to a sharp rise in \( v_0^4 \).

The normalization, \( N \), is given by

\[
N = \int_{v > v_{\text{cut}}} e^{-\psi/v_0^2} \frac{1}{v_0^4} d^3 v.
\]

The number density of the high velocity component which arrives at the Earth is given by

\[
n_{\text{e}}^0 = Nn_{\text{He}}^0,
\]

where \( n_{\text{e}}^0 = 0.2 \text{ cm}^{-3} \) is the number density far from the Earth [18].

Both \( v_0^4 \) and \( n_0^0 \) depend on the mirror helium density at the Earth’s surface, \( n_{\text{He}}(R_E) \) (through column density), which is set to \( n_{\text{He}} = 5.8 \times 10^{-11} \text{ cm}^{-3} \) [17]. There is also dependence on electron recoil energy, \( E_R \) (through \( v_{\text{min}} \)) and mirror electron temperature, \( T \) (through \( v_0 \)). Substituting Eqs. (8) and (10) into Eq. (5) to calculate differential rate introduces dependence on the kinetic mixing parameter, \( \epsilon \) (through \( \lambda \)) and the target material (through \( N_T \) and \( g_T \)). Calculation of the target independent parts \( v_0^4 \) and \( n_0^0 \) was validated by evaluating the differential rate for NaI. This was convolved with the expected detector resolution, assumed to be Gaussian with energy dependent width [19], in order to reproduce Fig. 4(a) from Ref. [17].

The differential rate of electron recoils in xenon could then be calculated using Eq. (5). If the shielding effects are not accounted for a Maxwellian velocity distribution is assumed for the mirror electrons, with the rate given by Eq. (6.4) of Ref. [15]. The differential energy spectra of electron recoils, calculated both with and without the shielding effects, are shown in Fig. 2 for a range of local mirror electron temperatures.

The low energy electron recoil response of the LUX detector was characterized using an internal tritium calibration, as described in [20]. The injection of tritiated methane into the gas circulation gave a large sample of electron recoils from beta decays in the energy range of interest, used to precisely measure light and charge yields in the detector. These yields show good agreement with the Noble Element Simulation Technique (NEST) package v2.0 [21]. Here we use NEST to model the distributions of the detector observables \( r, z, S_1, S_2 \), taking into account the detector resolution and efficiency, for signal events simulated using the above energy spectra. The quantities \( S_1 \) and \( S_2 \) are measured in photons detected (phd), with the resulting distribution in \( \log_{10} S_2 \) vs \( S_1 \) is shown in Fig. 3(a), for mirror electron temperature \( T = 0.3 \text{ keV} \) and kinetic mixing \( \epsilon = 10^{-10} \).

FIG. 1. \( v_0^4 \) as a function of recoil energy; constant at low energy due to independence from \( v_{\text{min}} \) rising steeply at higher energy where \( v_{\text{min}} \) exceeds the mean particle velocity.
IV. BACKGROUND MODEL

Interactions of mirror dark matter particles within LUX would induce isolated low energy electron recoil events. Consequently, the signal being searched for competes with background events that arise from Compton scattering of $\gamma$ rays from radioactive decay of isotopes in detector components, $\beta$ decay from $^{85m}$Kr, and Rn contaminants in the liquid xenon and x rays following $^{127}$Xe electron capture where the coincident $\gamma$ ray escapes detection [22]. Heavily down scattered decays from $^{238}$U chain, $^{232}$Th chain, and $^{60}$Co generate additional $\gamma$ rays from the center of a large copper block below the PMTs. The $\gamma$ rays can be modeled as two separate spatial distributions—one from below the bottom PMT array and one from the rest of the detector. Decays of $^{37}$Ar, by electron capture, within the fiducial volume are also included [8]. A fiducial radius of 18 cm is used to exclude low energy events from $^{210}$Pb on the detector walls. The full background model used in this analysis is shown in Fig. 3(b), with each component normalized to the expected value.

V. DATA ANALYSIS

A series of analysis cuts are applied to the data; events must also come from within a fiducial radius of 18 cm and z range of 8.5–48.6 cm above the bottom PMT array (drift time 305–38 $\mu$s). The S1 pulses in this analysis were required to have two PMTs in coincidence—at least two nonadjacent PMTs must measure an integrated area exceeding 0.3 phd. This is imposed to prevent spontaneous photocathode emission from being misidentified as an S1 pulse, as discussed in Ref. [13]. We also require $S_1^c$ size 1–80 detected photons and the raw $S_2$ size to exceed 165 detected photons. Corrected signal amplitudes $S_1^c$, $S_2^c$, account for nonuniform temporal and spatial response throughout the detector, based on $^{83m}$Kr calibrations. Position corrections mean that it is possible to have an S1 size below 2 phd, despite this twofold coincidence requirement. The data cuts leave 516 events in our region of interest, shown in Fig. 4 along with 90% signal contours. It should be noted that the signal model is not completely symmetric in $\log_{10} S_2^c$, so the contour containing 90% of the signal will not be exactly centered on the electron recoil band. This is a threshold effect due to the exponential shape of the signal model and is more pronounced for the sharply peaked signal models with no shielding.

The energy deposited by an event is given by [23]

$$E = W(n_e + n_\gamma) = W \left( \frac{S_1^c}{g_1} + \frac{S_2^c}{g_2} \right),$$

(11)

where $n_e$ and $n_\gamma$ are the number of electrons and photons produced, respectively, and $W = (13.7 \pm 0.2)$ eV is the work function for producing these quanta in liquid xenon. Gain factors $g_1 = 0.117 \pm 0.003$ phd/photon and
\[ g_2 = 12.1 \pm 0.8 \text{ phd/electron} \] were determined from calibrations [24].

Compatibility with the data is tested using a two sided profile likelihood ratio test with four physics observables: \( S_1 c, \log_{10} S_2 c, r, z \) [25]. Simulated distributions of the signal model and background model were generated for each observable. The distribution of the test statistic, the ratio of the conditional maximum likelihood (with number of signal events fixed) to the global maximum likelihood, is found for a range of numbers of signal events. This is used to calculate the p-value for each number of signal events. The hypothesis test is then inverted to find the 90% confidence limit on the number of signal events observed in the data. Systematic uncertainties in the background rates are treated as nuisance parameters. As detailed in Ref. [22], an extensive screening campaign gave the radioactive content of detector components, which was further constrained using data. Internal backgrounds were estimated from direct measurements of LUX data and sampling the Xe during the run. These were used to project the background rates for the period of data taking and normalize the Monte Carlo spectra. Nuisance parameters had the estimated rate as the mean value with a Gaussian constraint from the uncertainty. The best fit model covers zero signal model contribution for all mirror electron temperatures. The input and fit values for each nuisance parameter are shown in Table I, giving a total of 506 ± 32 background events, compared to 516 events in the data. For \( T = 0.3 \text{ keV} \), the background-only model gives KS test p-values of 0.27, 0.68, 0.71, and 0.60 for the projected distributions in \( S_1 c, \log_{10} S_2 c, r, z \), respectively. For \( T = 0.3 \text{ keV} \), this results in a 90% confidence limit of 11 signal events, although it should be noted that the background events extend over a larger energy range than the signal.

![Fig. 4. LUX data with contours containing 90% of the expected signal for mirror electron temperatures of 0.1 and 0.9 keV. Both are shown for kinetic mixing \( \varepsilon = 10^{-10} \), the solid line with shielding effects and the dashed line without.](image)

![Fig. 5. Upper limit on kinetic mixing, at 90% confidence level, as a function of local mirror electron temperature. The solid blue line shows this result, dashed blue is LUX sensitivity with green and yellow bands being 1 and 2\( \sigma \), respectively. The red line is the upper limit from orthopositronium decays [26], and the gray regions are disallowed by the theory.](image)

The 90% confidence limit on kinetic mixing parameter is then calculated using

\[
\varepsilon(90\%\text{CL}) = \varepsilon(0) \left( \frac{n\text{Sig}(90\%\text{CL})}{n\text{PDF}(0)} \right)^{\frac{1}{2}},
\]

where \( \varepsilon(0) \) is the arbitrary value of \( \varepsilon \) used to generate the signal model, \( n\text{PDF}(0) \) is the corresponding number of signal events, and \( n\text{Sig}(90\%\text{CL}) \) is the 90% confidence limit on the number of signal events. The power of 1/2 comes from the dependence of the rate on \( \varepsilon^2 \) in Eq. (4).

### VI. RESULTS

We set a 90% confidence limit on the kinetic mixing parameter, \( \varepsilon \), for the local mirror electron temperature range 0.1–0.9 keV, as shown in Fig. 5. The previous experimental constraint on \( \varepsilon \) comes from invisible decays of orthopositronium in a vacuum [26]. If positronium-mirror positronium mixing were to occur, decay to missing photons would leave a missing energy signal. The upper limit placed on the branching fraction of orthopositronium to

The 90% confidence limit on the kinetic mixing parameter is

\[
\varepsilon(90\%\text{CL}) = \varepsilon(0) \left( \frac{n\text{Sig}(90\%\text{CL})}{n\text{PDF}(0)} \right)^{\frac{1}{2}},
\]
infrared states gives a 90% upper confidence limit on the kinetic mixing parameter of $\epsilon \leq 3.1 \times 10^{-7}$. The astrophysical constraint on kinetic mixing within the mirror dark matter theory, $10^{-11} \leq \epsilon \leq 4 \times 10^{-10}$ [2], is also shown.

In Ref. [27], the XENON100 Collaboration examines the possibility of leptophilic dark matter models explaining the DAMA [28] modulation signal. For each model, the expected signal in xenon, given the DAMA modulation amplitude, is compared to XENON100 electron recoil data. This ruled out mirror dark matter as an explanation at a 3.6$\sigma$ confidence level, but there was no explicit search for mirror dark matter and no constraint was placed on the model itself.

VII. CONCLUSION/SUMMARY

We have presented the results of the first dedicated direct detection search for mirror dark matter. The effect of mirror dark matter captured by the Earth and subsequent shielding is included, for the first time, for a signal in Xe. A significant proportion of the parameter space allowed by the theory is excluded by this analysis. However, the present theoretical treatment makes assumptions for the local mirror electron temperature (thermal equilibrium with nuclei in the halo) and density [15,18]. The effect of deflection by the captured dark ionosphere is not included, and this could significantly alter the signal model.

Whilst there are possible caveats and extensions to this conceptually simple but phenomenologically complex mirror dark matter model, we have set limits based on the current model. This shows that it is possible to use direct detection experiments to probe low mass particles in a hidden sector.
