Abstract

The effect of the impeller designs and impeller clearance level (C/T) on power consumption, mixing time and air entrainment point in a single liquid phase under turbulent conditions (Re>10⁴) were investigated. Different impeller designs including conventional and new designs, were used to consider both axial and radial flow impellers. The electric conductivity method, suspended motor system and observation method were employed to determine the mixing time, the power consumption and the air entrainment point, respectively. The reduction in the impeller clearance level from T/3 to T/6 resulted in a decrease in power number values for up-flow pumping impellers while it was increased for down-flow pumping. The same trend was observed for the mixing time results. Moreover, axial flow impellers and specially HE3 are preferable for higher agitation speeds due to the less air entrainment. The results verified that the axial flow impellers and specifically down-flow impellers are more efficient than the radial flow impellers. ANFIS-Fuzzy C–means (ANFIS–FcM) and nonlinear regression were used to develop models to predict the mixing time based on the energy dissipation rate and clearance. The results verified that the model predictions successfully fit the experimental mixing time data.

Keywords: Impeller design, Clearance level; Energy dissipation rate; Mixing time; Nonlinear regression; ANFIS-Fuzzy C-means
1 Introduction

Mechanical agitation is widely employed in chemical process industries for heat and mass transfer applications or chemical reactions applications [1]. Precipitation, polymerization and hydrometallurgical processes are usually conducted using mechanical agitation. The efficiency of the mixing process is dependent on different internal parameters such as agitation speed, impeller type, tank geometry, geometrical ratios such as impeller to tank diameter (D/T), off-bottom clearance to tank diameter (C/T), liquid height to tank diameter (H/D), dispersed phase hold-up and fluid physical properties. Therefore, any small changes in vessel and impeller geometries has considerable effects on the power consumption, flow pattern, drop size distribution, mixing time and consequently on the mixing characteristics [2, 3]. In last 60 years, several impellers have been designed and developed for better efficiency in various applications but Rushton turbine, pitched blade turbines and propellers were the most common employed impellers [4-10].

Power consumption and mixing time are two parameters with a significant role in evaluating the performance of stirred vessels. Power consumption is defined as the required amount of energy per unit of time and mixing time is understood as the time required to obtain a certain degree of uniformity in a stirred vessel [3]. The stirred vessel configuration has a direct effect on these parameters and consequent influence on operating cost and product quality [1, 9, 11, 12]. Thus, the comparison of these parameters for various impeller designs and impeller off-bottom clearance level gives valuable information about the performance of the agitation systems [1, 13]. Furthermore, it is also helpful to improve and develop the design of reactors especially when the geometrical design and the condition of experiments are comparable. However, achievement of desired level of mixing is expected at the lowest value of the power consumption [5].
Several studies have been accomplished on the effect of impeller designs and configurations on mixing parameters. Raghav Rao and Joshi [14] performed extensive experiments to study the effect of clearance for different design of impellers on the power consumption per unit volume of liquid and pointed out better efficiency for down-flow pitched blade turbine. They reported a reduction in mixing time with decreasing the clearance for disk turbine and pitched blade up-flow turbine while it was increased in the case of pitched-blade down-flow turbine. Rewatkar and Joshi [14] also studied the effect of impeller clearances and impeller designs on mixing times. They reported that the pitched blade turbine both down-flow and up-flow are more energy efficient than the disk turbine design at equal power consumption per mass. They also stated the same dimensionless mixing time for all of these impellers. The variety in relative performance was due to the different values of impeller power number. They also indicated a decrease in mixing time with increasing the blade angle for pitched blade turbines and the PBTD45 was the most efficient one. Further increase was observed for mixing time with decreasing the impeller diameter [5]. Rzyski [15] reported lowest mixing time for propeller among a six blade disk turbine (DT), propeller (with two different pitches), and six-blade fan-type turbine at equal power consumption. The results verified that the performance of axial flow impellers is close together and their mixing time is lower than radial flow turbines. Ruszkowski [16] found the same mixing time was observed for pitched blade turbines with different blade numbers and blade angles, six blade DT and propeller at equal power consumption. Moreover, a large diameter with low power number was suggested as the most energy efficient one in turbulent mixing. Distelhoff et al. [17] reported the same results with Raghav Rao and Josi [14] and Rewatkar and Joshi [5] with lower mixing times for the down-flow pitched blade turbine than the radial flow impeller. Houcine et al. [1] also reported an increase in mixing time values with
decreasing the clearance from T/2 to T/3 for pitched blade turbine while decreasing for Rushton
turbine and MIXEL propellers.

Nere et al. [2] performed extensive experiments to examine the effect of different impeller
and tank geometries on the mixing times. They stated that the dimensionless mixing time
changes reversely with the cube root of the power consumed per unit volume of the liquid. The
constant was obtained at 7.9 for the disk turbine while it was 4.38 for the propeller. The results
were inconsistent with the outcomes presented by kramers et al. [4]. They notified that the
clearance level is dependent to the impeller designs and tank geometries. They recommended to
use C/T=1/3 in the case of PBTD, DT and marine propeller inline to other previous studies [2].

Kumaresan and Jushi [7] found that, irrespective of the impeller design, the mixing time was to
be inversely proportional to the secondary flow number \(N_{QS}\) for 18 different designs of
impellers including PBT, Hydrofoil impellers and Rushton turbine with variances in blade angle,
number of blades, blade width, blade twist, and blade thickness through LDA measurement.
They indicated 3% less power number and 7% reduction in average normal stress at the higher
clearance level for PBTD turbine which resulted in higher mixing time [7]. Aubin et al. [18]
obtained that the axial up-pumping flow impellers reduce the mixing time and increase
turbulence in batch reactors through CFD modeling. Ochieng and Onyango [12] showed that the
flow pattern for the Rushton turbine changed from the typical two loops to a single loop similar
to axial flow impellers at the low off-bottom clearance which was caused in a lower mixing time
at a constant power number`. Woziwodzki [19] achieved higher mixing time in an un-baffled
vessel compared to the baffled vessel for turbine impeller. Afshar Ghotli et al. [20] investigated
various curved blade impellers and indicated higher power number for wider curvature blades.
Moreover, lower power consumption was observed for the curved blade impellers compared with the Rushton turbine.

Several correlations have been developed to predict the mixing time within the stirred vessels to estimate the mixing efficiency. Some of these correlations were derived based on the dimensionless mixing time. Dimensionless mixing time ($N_{tm}$) is depended on the impeller and tank geometries in turbulent condition [21]. However, most of the correlations have been developed based on the mixing time. The effect of Froude number and Reynolds number can be neglected under the turbulent condition. Prochazka and Landau [22] developed correlations to estimate the mixing time for Rushton turbine, propeller and pitched blade, separately, for a standard stirred vessel under turbulent conditions [23]. One of the best correlations between the mixing time and power consumption per unit volume was suggested by Moo-Young et al. [24] and Nienow [25]:

$$t_m = c\left(\overline{\epsilon_f}\right)^d$$  \hspace{1cm} (1)

The value of “d” was found approximately $–0.33$ for turbulent regime in many studies. The value of “c” can be determined experimentally, and it is depended on the impeller and vessel geometry. Pakzad et al. [26] reported the value of “c” and “d” at 113.3 and $–0.33$ for transient regime, respectively. Woziwodzki [19] found the value of 3.9 for the “c”. Van riet and Tramper [27] derived a theoretical correlation [25]:

$$t_m N = 3 \left(\frac{D}{T}\right)^{-3} N_p^{-1/3}$$  \hspace{1cm} (2)

Ruszkowski [16] and Grenville et al. [28] developed correlation (3) to estimate the mixing time for various impeller geometries at $H=T$ and energy dissipation rates of 1 W/kg [29]

$$t_m = c \left(\frac{1}{N} \right) \left(\frac{1}{N_p^{1/3}}\right) \left(\frac{D}{T}\right)^{-2}$$  \hspace{1cm} (3)
The value of “A” was defined by Ruszkowski [16], Grenville et al. [28] at 0.53. Thus;

\[ t_m = 5.9T^{2/3} \left( \bar{\varepsilon}_r \right)^{-1/3} \left( \frac{D}{T} \right)^{-1/3} \] (4)

A good agreement was found for this equation with different impellers with different ratio of D/T [25, 30-32].

Pandit and Joshi [33] developed the equations to estimate mixing time on the basis of flow pattern for DT, PTD and PTU, respectively [14]:

\[ t_m = 9.43 \left( \frac{1}{N} \right) \left( \frac{aH + T}{T} \right) \left( \frac{T}{D} \right)^{13/6} \left( \frac{W}{D} \right) \] (5)

\[ t_m = 5.0 \left( \frac{1}{N} \right) \left( \frac{2H}{D} + \frac{T}{D} \right) \left( \frac{C}{D} \right) \] (6)

\[ t_m = 5.0 \left( \frac{1}{N} \right) \left( \frac{2H}{D} + \frac{T}{D} \right) \left( \frac{H - C}{D} \right) \] (7)

Rewatkar and Joshi [5] developed a correlation for pitched blade turbine to show the effect of impeller blade angle (A), a ratio of blade width to impeller diameter (W/D), number of blades (n_b), a ratio of tank diameter to impeller diameter (T/D), a ratio of impeller clearance to tank diameter (C/T) and a ratio of liquid height to tank diameter (H/T) on mixing time.

\[ t_m = 5.37 \left( \frac{1}{N} \right) (A)^{-0.87} \left( \frac{W}{D} \right)^{-0.314} (n_b)^{-0.482} \left( \frac{T}{D} \right)^{1.83} \left( \frac{C}{T} \right)^{-0.27} \left( \frac{H}{T} \right)^{0.413} \] (8)

Though, several studies on the effect of impeller design on mixing efficiency can be found through the literature, few of them considered a wide range of impeller designs. Accordingly, the purpose of this effort is to provide the macromixing reports for different impeller designs. The effect of impeller types, impeller clearance and agitation speed on mixing time, power consumption and air entrainment point has been studied. Various design of impellers namely
Rushton turbine (RT), up-flow pitched-blade turbine (PBTU), down-flow pitched-blade turbine (PBTD), semicircular blade (CB), parabolic blade (PB), axial flow hydrofoil impeller (HE3) and newly designed double circular blade (DCB) have been employed. The present work aims to evaluate the efficiency of various impellers at different clearance levels with regard to the variation of the power consumptions and mixing times for turbulent system (Re > 10^4). In addition to the experimental study, the purpose of this work is to provide accurate models to predict the mixing time based on attributes of different impeller designs off-bottom clearance. Therefore, non-linear regression method and adaptive neuro-fuzzy inference system, based on fuzzy c–means clustering algorithm (ANFIS–FcM) were applied in order to determine the relationships between input and output parameters. These methods are followed to develop accurate models to predict the mixing time and to discuss the results.

2 Materials and Experimental setup

2.1 Set up

A flat-bottomed agitated vessel with a volume of 0.022 m^3 (22 L) and an internal diameter of 0.3 m were used for all the measurements. Four removable wall mounted baffles were fitted equally spaced. Different designs of impellers including Rushton turbine (RT), 45° up-flow pitched blade turbine (PBTU), 45° down-flow pitched blade turbine (PTBD), semi-circular blade (CB), parabolic blade (PB), hydrofoil (HE3) and newly designed double circular blade (DCB) impellers, were employed. The hydrofoil design is disclosed in European Patent EP 0 465 636 B1. Fig. 1 and Fig. 2 illustrate the schematic of experimental setup and impeller designs, respectively. The pitched blade turbines hydrofoil impeller are belonging to the axial flow impellers. These impellers provide suction and pumping in a direction parallel to the shaft axis [34]. The hydrofoil impeller is designed in 3-bladed impeller while the pitched blade turbines
have 6-blade with 45° angle. Besides, the Rushton turbine, semi-circular blade, double circular blade, parabolic blades are radial flow impellers. The suction flow is in a direction parallel to the shaft axis while pumping is normal to the shaft [34]. All of the radial impellers are provided in six-bladed designs. The ratio of impeller diameter to the tank diameter is equal to 1/3 for all of the impellers. The ratio of impeller clearance (C) to the tank diameter (T) set at T/3, T/4 and T/6. The rotational speed is varied in a range of 1.67 rps to 15 rps to provide the turbulent flow regime. The vessel was filled with distilled water as a working fluid and the liquid height was equal to tank diameter (H=T). Distilled water with a viscosity of 0.001 kg/ms, density of 998.00 kg/m³ and interfacial tension of 71.90 mN.m⁻¹ was used. The temperature of the water was controlled and all the measurements were carried out at the room temperature (24 °C).

Fig. 2. The used impellers in experimental part: (a) RT, (b) CB, (C) PBTU, (d) PBTD, (e) EB, (f) PB, (g) HE3, (h) DCB [35]

2.2 Determination of power consumption and power number (N_P)

The power consumption and power number values for all of the impellers were obtained at turbulent Reynolds number. It was measured directly from the motor using the power analyzer, to compare the efficiency of different impeller design:

\[
N_p = \frac{P}{\rho N^3 D^5}
\]  

(9)

Where “P” is Power required by the impeller, kg m²/s³; “N” is impeller rotational speed, rev/s, “\(\rho\)” is liquid density, kg/m³ and “D” is impeller diameter, m.
The power consumption is extremely dependent on Reynolds number [1, 36, 37]. Reynolds number (\(N_{\text{Re}}\)) is demonstrated in equation 10 which reveals the ratio of inertial forces to viscous forces.

\[
N_{\text{Re}} = \frac{\rho ND^2}{\mu}
\]  

(10)

Where “\(\mu\)” is the liquid viscosity, kg/s m.

The mean energy dissipation rate can be obtained through the following expression [11]:

\[
\bar{\varepsilon} = \frac{P}{V_T \rho} = \frac{N_{\beta} N^3 D^5}{V_T}
\]  

(11)

Where “\(V_T\)” is the tank volume, m³.

2.3 The point of air entrainment

The impeller speed at which air is entered from the surface of a stirred vessel for the first time, is the air entrainment point \(N_E\). The air entrainment point is very important for several applications. In some applications air entrainment is not desirable and then a large \(N_E\) is needed whereas for the others air is needed for more efficient processes and therefore, a small \(N_E\) is desirable [38]. Air entrainment is taken place by interaction between the interfacial tensions and the turbulent eddies at the surface of stirred vessel [39]. The \(N_E\) characteristics let to perform a comparison on the amount of turbulence at the tank surface between various impeller geometries. In the current study, air entrainment point was determined by observation of the liquid surface as the point bubbles were started to entrain.

2.4 Determination of mixing time

The mixing time is experimentally defined by measurement of the concentration of injected tracer within the stirred vessel. The concentration in the mixing tank is changed by tracer
injection. Macromixing or bulk blending time is defined when the concentration at the measuring points reach to 95% ΔC. The conductivity is the most common method to measure the mixing time. Therefore, it was applied to measure the mixing time in the current study. In this method, an electrolyte is added through the vessel as a tracer to monitor the local conductivity against the time. Solution of NaCl is used as an electrolyte commonly. 10 mL of NaCl Solution (250g/L) was injected to the tank through the liquid surface, 30 mm from the wall through a syringe [1, 10, 19]. Two conductivity Suntex, EC.430 probes (Taiwan) with the accuracy of ±1% were fitted to the wall; one was located at the opposite position of the injection point 80 mm lower than the liquid surface and the other one was 80 mm over the bottom.

The conductivity outputs are used to evaluate the mixing time [40]. The time elapsed between the injection of tracer and the point when the instant conductivity attained within 95% of its final value is considered as the mixing time for each probe [1].

\[
Y = \left| \frac{C(t) - C_0}{C_\infty - C_0} \right|
\]  

(12)

Where “\(C(t)\)” is the concentration of the trace at time (t), “\(C_0\)” is the initial and “\(C_\infty\)” is the final average concentrations of tracer. Each test is repeated 3 times to get an average of the mixing time.

The mixing efficiency (\(\eta\)) of the system can be obtained through the calculation of mixing time (\(t_m\)) and mean specific energy dissipation rate (\(\bar{\varepsilon} \)) through the following expression [11]:

\[
\eta = \bar{\varepsilon} t_m
\]

(13)
2.5 Mixing time prediction

2.5.1 Non-linear regression method

Mixing time and power consumption were obtained for each impeller at three different off-bottom clearances (T/3, T/4 and T/6) and a range of speed from 1.67 rps to 15 rps. The general form of the relation between the mixing times, energy dissipation rate and impeller clearance in single phase liquid system was derived from the literature as follows [5, 24, 25];

\[ t_m = \alpha \left( E^{-\beta} \right) \left( \frac{C}{T} \right)^\gamma \]  

(14)

The experimental data were then fitted to the previously mentioned mixing time model to determine the corresponding model parameters for each impeller. The transformation of nonlinear equations into linear forms is generally associated with the error distribution, depending on the method used to linearize the equations [41, 42]. Therefore, in this study, a non-linear regression analysis using the Marquardt–Levenberg algorithm was employed in SigmaPlot software version 12.0 (Systat Software Inc., USA) to determine the parameters associated with the clearance and energy dissipation rate variables in the mixing time correlation. The nonlinear coefficient of determination \((R^2)\), was evaluated to quantitatively compare the goodness of fit of the abovementioned model (Eq. 14) to the experimental data and adjust each set of mixing time model parameters. The coefficient of strength of character, which determines how well the data points fit the model, was calculated as follows [43];

\[ R^2 = 1 - \frac{\sum_{i=1}^{n} (t_{m(\text{meas})} - t_{m(\text{cal})})^2}{\sum_{i=1}^{n} (t_{m(\text{meas})} - \bar{t}_{m(\text{meas})})^2} \cdot \frac{(n-1)}{(n-p)} \]  

(15)

Where \( \bar{t}_{m(\text{meas})} \) is the experimental data average value; and “\( p \)” is the number of model parameters.
2.5.2 ANFIS-Fuzzy C-Means

A fuzzy inference system may be employed towards mimicking specific features of human supervisory know-how to complete duties and avoiding to use comprehensive mathematical calculations. Neural networks (NNs) are in fact mathematical models to process data which are inspired by how a brain works. NNs, similar to the brain neurons, contain various interconnected computing cells. The training process of NNs ascertain a relationship is constructed between the input and output data [44]. Amalgamation of fuzzy logic (FL) with NNs has demonstrated potential of these structures in basically imitating the actual sequence of decision-making that a professional follows in comparable situations. The weight values of the interconnections varies throughout the training phase of the traditional NNs, however, in the hybrid designs of the FL and NNs, the learning capability of NN and the inference mechanism of the FL is combined towards a unified neuro-fuzzy supervisory system [45].

A neural network structure which comprises of numerous coupled nodes through indicator associations is an adaptive network. Each node is described by a node function with constant or variable parameters. In order to reduce the error, NN algorithms are utilized to discover the undetermined preliminary and succeeding rule parameters of the FL. The full details of the ANFIS method is given by Jang et al. [46].

In addition, in this work, Fuzzy C-means (FcM) is applied. FcM, introduced by Bezdek [47], is a data clustering method which permits one data portion to correspond to two or more clusters. Deciding on the how to categorize data from dataset in order to give a brief image of a system's performance is the objective of data clustering [47]. FcM distributes a set of $n$ vector $X_i$, $i=1,2,\ldots,n$, into C fuzzy groups and identifies a cluster center in each one while minimizing a difference measure cost function.
The FcM algorithm steps can concisely be described as follows. Initially, the cluster centers \( c_i, \ i = 1, 2, \ldots, C \) are chosen arbitrarily from the \( n \) points \( \{X_1, X_2, X_3, \ldots, X_n\} \). Then, the membership matrix \( U \) is computed using the following equation:

\[
\mu_{ij} = \frac{1}{\sum_{k=1}^{c} \left( \frac{d_{ij}}{d_k} \right)^{m-1}}
\]

(16)

where, \( d_{ij} = \|c_i - x_j\| \) is the Euclidean distance between the \( i \)th cluster center and \( j \)th data point, and \( m \) is the fuzziness index. Next, the cost function according to the following equation is computed. The process is stopped if it is below a certain threshold.

\[
J(U, c_1, \ldots, c_2) = \sum_{i=1}^{c} J_i = \sum_{i=1}^{c} \sum_{j=1}^{n} \mu_{ij}^m d_{ij}^2
\]

(17)

In the final step, a new \( c \) fuzzy cluster centers \( c_i, \ i = 1, 2, \ldots, C \) using the following equation is computed:

\[
c_i = \frac{\sum_{j=1}^{n} \mu_{ij}^m x_j}{\sum_{j=1}^{n} \mu_{ij}^m}
\]

(18)

By using a part of the experimental data and FcM-based ANFIS approach, the model showed to be able to anticipate the mixing time. The target parameter in the model was the mixing time while the tank clearance and the mean energy dissipation rate were chosen as the design parameters. In order to develop the model, the experimental data points were separated into 70%, 15% and 15% segments for training, validation and test respectively. Table 1 encapsulates the specifications of the designed ANFIS-FcM model.

**Table 1.** Specifications of the developed ANFIS-FcM model for mixing time prediction
3 Results and Discussion

3.1 The effect of impeller design on power number

The power number of each impeller was determined through direct measurement of the required power, $P$, to drive the impeller. The accuracy of the measurement method was verified by comparing the power number values for commonly used impellers with the literature. The variations of power number with Reynolds number for given impellers in this work at $C=T/3$ are illustrated in Fig. 3. All the experiments were carried out in a Reynolds number range of $5.0 \times 10^4$ to $15.0 \times 10^4$. The results showed that at the same geometry and agitation speed, the power number ($N_p$) for the hydrofoil impeller (HE3) at $C=T/3$ was 0.36 whereas for PBTD, PBTU, PB, EB and CB were 1.19, 1.75, 2.28, 2.96 and 3.25, respectively. The DCB and RT are ranked last with the values of 6.76 and 5.55. The results proved the power number of DCB and RT are almost 10 times than that of the hydrofoil impeller. The results indicated that the axial flow impellers and specifically the down-flow impellers have the lowest power number values among the impellers. The results clearly showed a reduction in the power number values for the radial flow impellers as the blade curvature increases. Moreover, the disk turbines have higher power number values than the impellers without central disk. The experiments indicate that for a given impellers, the power number did not vary in a turbulent regime, significantly. However, slight changes can be seen due to instability of the measurement device. The flow pattern has a significant role on power consumption and any changes on flow direction affect the power number value [48]. A tendency of the bubbles to accumulate at the low-pressure area leads to extend the gas cavity effect and conducts in a higher power values under un-aerated condition [49]. The high volume of air bubbles around the impeller region for the radial flow impellers
such as RT and DCB leads to an increase in the cavity effect and higher power consumption at higher Reynolds numbers. Therefore, any parameter that makes an alteration in the flow or turbulence, changes the power consumption.

Fig. 3. Comparison of $N_p$ values for DCB (○), RT (♦), CB (■), EB (△), PB (●), PBTU (◇), PBTD (▲) and HE3 (□) at $C/T=1/3$

### 3.2 The effect of impeller off-bottom clearance on power

The effect of clearance on impeller power consumption at three common clearance levels including $1/3T$, $1/4T$ and $1/6T$ were tested. Furthermore, the effect of clearance on mean energy dissipation rate for all impellers at different agitation speed, from 1.67 to 8.33 rps, were examined and plotted. Fig. 4 illustrates a typical impellers trend at 5 rps. In case of disk turbines, the value of impeller power number decreased with reduction in the clearance level from $T/3$ to $T/6$. The disc causes higher kinetic energy in the entrained flow at a clearance of $T/3$ compared with the lower clearance. The turbulent energy dissipation rate increases with an increase in the path length in a turbulent flow, which improves the impeller pumping and reduction in the power consumption [48]. For the RT, CB, EB, PBTU and PB a decrease in the off-bottom clearance from $T/3$ to $T/6$ led to lower power number value whereas an increase was observed in the power number values for PBTD and HE3. Also, a decrease in the clearance level led to shorter loops for return flows in the up-flow turbines. Therefore, the flow has a higher energy which leads to better impeller pumping and further reduction in impeller power number. Rewatkar and Joshi [5], Rao and Joshi [14], Rewatkar et al. [48] and Zhao et al. [50] also reported the same trends for PBTD and PBTU with decreasing clearance level. The reduction in clearance leads to an increase in cross flows below the impeller area and higher velocity rate. In lower clearances, the impeller output flow hits the tank bottom and changes the flow direction significantly,
consequently leading to higher energy dissipation rate and higher power number in down flow impellers. The results for the DCB impeller at different clearance levels showed a significant reduction in power number at level T/6 while for HE3 were mostly the same at different clearances.

**Fig. 4.** The effect of clearance on power number in various impellers; (a) RT, (b) CB, (C) PBTU, (d) PBTD, (e) EB, (f) PB, (g) HE3, (h) DCB

The mean energy dissipation rate, $\varepsilon$, for the CB and EB configurations were 42% and 29% larger than the PB at T=1/3 and 5 rps. The mean specific energies for the PBTU were 42%, 28% and 3% larger than the PBTD at T/3, T/4 and T/6, respectively. However, the lowest values were found for the HE3 among the studied impellers.

3.3 The effect of impeller design and clearance on Air entrainment speed

The influence of impeller design and clearance on $N_E$ is illustrated in Fig. 5(a) for all the studied impellers except for the HE3. Although, the test continued up to the speed of 20 rps for the HE3 impeller, no any bubble was observed within the tank. The point of air entrainment $N_E$ is influenced by both the impeller type and the impeller clearance. The axial flow impellers mostly can be used for higher agitation speed. The surface aeration was observed after 16 rps for the Hydrofoil impeller, and for the PBTU and PBTD after 11.6 and 7 rps, respectively. For the radial flow impellers, the highest air entrainment speed was observed for the EB after 7.5 rps. The $N_E$ values were observed in a range of 5 to 7 rps. The flow stream moves in two separate loops from the walls towards the shaft near the liquid surface for the radial flow impellers. The loops are created around the impeller blades in lower speed while they increase toward the tank wall and top surface, causing the sucking of air bubbles inside the liquid wall [51]. In the case of
axial flow impellers, the flow for the down flow impeller (PBTD) is created one loop toward shaft near the liquid surface and discharges the flow in the downward direction. However, for the up-flow impellers, PBTU and HE3, the flow is pumped upward along the shaft toward the surface and then circulates along the tank wall. This flow then loses its intensity and changes to a weak flow below the impeller. In the down flow impellers, the gas bubbles are drawn down into the central section of the tank and then distributed radially toward the tank wall and surface [51]. Therefore, air entrainment for radial flow impellers and PBTD is different compared to PBTU and HE3 [52].

Bhattacharya et al. [38] reported that increasing the submergence caused a higher $N_E$ which was in a good agreement with our obtained results. Decreasing the impeller clearance reduced the turbulent energy reaching the surface, resulting in a higher agitation speed to make bubbles at the liquid surface. In the present study, this trend was observed for all the given impellers except for the PBTU. This can be attributed to its upward flow pattern which pumps flow stronger in lower clearances. The DCB impeller has a smaller $N_E$ and is less sensitive to clearance. For the EB, CB and PB, the $N_E$ shows a fairly similar values and trends. In the case of up-pumping impellers, a stronger discharge flow into the surface is generated in comparison with the down pumping impellers. Thus, the lower power consumption has been obtained at lower clearances for pitched blade up-flow impeller. The high velocity under the down flow impellers causes the fluid to move along the bottom and then the top of the tank. Because of low-pressure regions behind the impellers, the fluid does not move in a direct path to the surface, resulting in poor circulation and mixing in the top of the tank [53].

Fig. 5(b) represents the mean energy dissipation rate for the impellers at the air entrainment point. As expected, the mean energy dissipation rate was increased with decreasing the clearance
level, except for the PBTU. Although, the results for the PBTU at T/3 were higher than the PBTD, with decreasing the clearance, PBTU showed lower energy dissipation rate than the other impellers.

For the application where air entrainment is desired, $N_E$ is a proper parameter to make a comparison between the impellers. Therefore, the PBTD provides the best performance with the lowest $N_E$ and power consumption.

3.4 Mixing time

3.4.1 Effect of various impeller type on mixing time

The mixing times were obtained for impeller agitation speeds of 1.67 to 8.33 rps, corresponding to Reynolds numbers of $5.0 \times 10^4$ to $15.0 \times 10^4$ at clearance level of (T/3) for all the studied impellers. Due to high air entrainment within the tank, the experiments were stopped at 8.3 rps for all of the impellers, except for the DCB. For the DCB, the experiment was stopped at 6.6 rps because of high air entrainment within the tank above this speed. Fig. 6 illustrates the results for mixing time against Reynolds number. The measurements proved the close mixing time values after $Re=6.7 \times 10^4$ for all axial and radial impellers except for the hydrofoil impeller. Similar observation was made by Biggs, [54] and Rewatkar and Joshi [5] and Fentiman et al. [55].

Fig. 6. Mixing time against Reynolds number for various impellers
The graph illustrates that the DCB turbine can reach the desired mixing point at lower Reynolds numbers while the mixing time values for the Hydrofoil impeller were 2 to 4 times higher than the other impellers within the selected range of Reynolds number.

The experiments were conducted at the same power consumption to find out the effect of impeller design on the mixing time. Fig. 7 represents the comparison of the mixing time for each impeller at the same power consumption per volume (P/V) at T/3. The figure indicates that the highest mixing time values at the same power consumption were obtained for the radial flow impellers while the lowest were found for the axial flow impellers. The results verified very close values for the radial and axial flow impellers in a range of 10.0 to 12.3 (s) and 7.6 to 8.9 (s). The best performance was observed for the PBDT. Very close values were also obtained for the elliptical blade and curved blade impellers at the same power consumptions. Shorter mixing times were predicted for the higher discharge rate impellers because of faster circulation within the tank. In the case of radial flow impellers, the mixing time values increased as the blade becomes more curved and therefore, mixing time values for the elliptical and parabolic blade turbines was higher in comparison with curved blade and Rushton turbine. Therefore, the obtained results prove the effect of flow diagram in the tanks influence the mixing efficiency.

Fig. 7. Comparison of the mixing time for different impellers at the same power consumption (P/V=160 W/m³)

3.4.2 Effect of Clearance on mixing time

The effect of off-bottom clearance on mixing time in the mixing vessels was studied for each type of impellers through the T/3 to T/6 at 5 rps. As seen Fig. 8, for the pitched blade down-flow impeller and hydrofoil impeller, the value of mixing time increased with a decreasing clearance from T/3 to T/6. However, for the other impellers, the mixing time was found to
decrease when the clearance was decreased from T/3 to T/6. The plot signified that the highest mixing time value was obtained for the HE3. In contrast, the PBDT shows better performance and it can be a good choice even in lower clearance due to the lower power consumption compared with radial flow impellers. In the case of HE3 and PBTD, decreasing the clearance from T/3 to T/6 caused the generation of smooth flow and lower circulation velocity, which resulted in higher mixing time values. Decreasing the clearance for the PBTU leads to a larger circulation velocity and a better suction through tank and a lower mixing time value [14]. Decreasing the mixing time values in radial flow impellers with decreased in the clearance level can be described with a larger path length and flow rate in the area on the top of the impeller. The suction is divided by the disk and causes larger circulation velocities through upper and lower loops in the tank, resulting in smaller mixing times. Moreover, as the blade becomes more curved the slope of stream becomes smaller and causes a weaker radial jet. This resulted in higher mixing times in elliptical and parabolic blade turbines in comparison with curved blade and Rushton turbine [50].

Fig. 8. The effect of impeller clearance on mixing time at 5 rps

3.4.3 Correlation study

3.4.3.1 Empirical Correlation

As previously stated, the mean energy dissipation rate and the off-bottom clearance are two significant variables that affect the mixing time. Thus, in the modeling of the mixing time in the current study we implemented an approach that considers the effect of variation in clearance as well as the variation in the mean energy dissipation rate due to the speed variation. The main distinguishing feature for choosing a suitable model arises from the accuracy as well as simplicity of the equations. Therefore, equation 14 was derived as a general form of the relation
between the mixing times, energy dissipation rate and impeller clearance in single phase liquid
system from the literature. The experimental mixing time data were fitted to the abovementioned
mixing time model and the corresponding parameters for each impeller were then adjusted.

For each studied impeller, a non-linear regression method was employed to independently
define the parameters according to the Equation 14. Table 2 represents the optimal values of the
model parameters. As evident in this table, the model parameters for each impeller varied when
the off-bottom clearance and the energy dissipation rate were changed.

Furthermore, the nonlinear regression coefficient ($R^2$) were evaluated and tabulated in Table
2 to quantitatively compare the quality of this method. The calculated values of $R^2$ verify the
capability of the recommended model to fit the experimental mixing time data for various
impellers at different experimental conditions. Fig. 9 illustrates the quality of the fit of this model
to the experimental data for studied impellers. The surface attained from the global fitting of the
above-mentioned model to the experimental data verifies that the experimental data are described
well for all clearance levels and energy dissipation rates when the mixing time plotted in
proportion to the proposed model used.

Table 2. Calculated values of the model parameters and associated $R^2$ for each impeller

Fig. 9. Graphical representations of the fit of the experimental data to the developed mixing
time model for all studied impellers

3.4.3.2 ANFIS-FcM model

As mentioned before, ANFIS–FcM was utilized in this study to build a substitute prediction
model to predict the mixing times from experimental data. The codes were written in the
MATLAB environment and a loop was defined in order to repeat the model development if the
final $R^2 \leq 0.999$. A dataset including 120 points was engaged. The predicted values for the mixing times by the ANFIS–FcM model in comparison with the measured values of mixing times is presented in Fig. 10.

**Fig. 10.** Prediction capability of ANFIS-FcM model vs. experimental data for the whole dataset

Fig. 11 represents evaluation of the estimated values of mixing time by the ANFIS-FcM model and Non-linear regression models. The regression plot proves FcM capability over the non-linear regression model when the results are compared to the experimental data points.

**Fig. 11.** Cross plot of predictions of ANFIS-FcM model and Non-linear regression model

### 4 Mixing efficiency

The mixing efficiency ($\eta$) was evaluated with considering both mixing time and the mean energy dissipation rate on different clearance and agitation speeds. The mixing efficiency ($\eta$) for the single-phase system can be evaluated through the equation (13) which has been derived by Ochieng & Onyango [11].

Clearly, lower values of ($\eta$) verify better efficiency within the mixing tank. Fig. 12 shows the P/V and the mixing time against the mixing efficiency values ($\eta$) at the clearance of T/3. The graph shows that increasing the power consumption and mixing time lead to higher value for $\eta$. On the other hand, the efficient systems are considered to be those that can reach the desired level in lower mixing time and power consumption. Moreover, the same value of $\eta$ for each impeller can be seen at the intersection point of the two trend lines. This point is therefore assumed to be an efficient point for each impeller. With this assumption, the efficient points were attained for the axial flow impellers and especially for the hydrofoil and pitched blade
down flow turbines. The lowest efficiencies were obtained for the RT, CB and DCB. The performance of elliptical and parabolic blade shape was nearly the same. The calculated results provide a good comparison in the form of mixing time and energy dissipation rate for industrial purposes. The results confirmed that the axial impellers like pitched blade impellers are more efficient in liquid mixing compared to the radial flow turbines. Furthermore, the hydrofoil impeller can be a good choice for the process which needs slow bulk motions such as water treatment plants.

Fig. 12. The efficiency of impellers values ($\eta$) against the P/V and the mixing time at the clearance of T/3

5 Conclusion

Dispersion characteristics of various impeller designs through different off-bottom clearance levels were investigated by power consumption, mixing time and air entrainment point. In addition to the experimental study, accurate models were developed to predict the mixing time using non-linear regression method and ANFIS–FcM method. Four common impeller types in addition to three rarely used were chosen. A new curved blade impeller design was also developed for further studies. All the experiments were carried out in single liquid phase system and varying Reynolds number and agitation speeds. Reduction in power consumption was observed for the radial flow impellers as the blade’s curvature increased. The lowest power numbers were obtained for the down flow impellers like HE3 and PBTD. Decreasing the off-bottom clearance from T/3 to T/6 led to lower power numbers for the up-flow impellers, whereas an increase was observed for the downward flow impellers. The results for air entrainment speed ($N_E$) showed that the DCB and RT reach to $N_E$ very fast. The mixing time values for the DCB were the smallest whereas PBTD, RT, PBTU, CB, EB, PB, and HE3 were ranked after it,
respectively. The results indicated that the efficiency of pitched blade turbines were better than
the other impellers. Investigation on the effect of clearance on the mixing time demonstrated an
increase in the mixing time with decrease the clearance from T/3 to T/6 for PBTD and HE3
whereas it was decreased for the other studied impellers. The obtained results provide a good
comparison in the form of mixing time and energy dissipation rate at different clearance levels
for industrial purposes. The results confirmed better efficiency for axial-flow impellers
especially for down-flow ones. The results of the correlation studies revealed more accurate
predictions through the Anfis-FcM model compared to the regression method.
