34 **Abstract**

35 Large-scale biodiversity change is measured largely through the responses of a few taxonomic groups.
36 Much less is known about the trends affecting most invertebrates and other neglected taxa, and it is
37 unclear whether well-studied taxa, such as vertebrates, reflect changes in wider biodiversity. Here, we
38 present and analyse trends in the UK distributions of over 5,000 species of invertebrates, bryophytes
39 and lichens, measured as changes in occupancy. Our results reveal substantial variation in both the
40 magnitude, direction and timing of change over the last forty-five years. Just one of the four major
41 groups analysed, terrestrial non-insect invertebrates, exhibit the declining trend reported among
42 vertebrates and butterflies. Both terrestrial insects and bryophytes & lichens increased in average
43 occupancy. A striking pattern is found among freshwater species, which have undergone a strong
44 recovery since the mid-nineties following two decades of decline. We show that, while average
45 occupancy among most groups appears to have been stable or increasing, there has been substantial
46 change in the relative commonness and rarity of individual species, indicating considerable turnover in
47 community composition. Additionally, large numbers of species experienced substantial declines. Our
48 results suggest a more complex pattern of biodiversity change in the UK than previously reported.

49 **Background**

50 Large-scale study of the state of biodiversity is key to ensuring that conservation actions are targeted
51 appropriately. However, high quality population time series collected on an annual basis are typically
52 restricted to birds¹, other vertebrates² and butterflies^{3,4}. Most invertebrates do not feature in studies of
53 large-scale biodiversity trends^{2,5} and it is unclear whether these well-studied groups reflect changes in
54 wider biodiversity⁶⁻⁸. Invertebrates and plants constitute a substantial portion of biodiversity and
55 support many ecosystem functions, so their lack of representation could mean that important trends are
56 being overlooked. Recent concern about the status of under-studied groups, particularly insects⁹⁻¹² has
57 been echoed by concerns about the quality of available evidence^{13,14}. Thus, there is an urgent need to
58 mobilise existing data and interrogate them with modern, rigorous analysis tools.

59 Here, we explore long-term change in UK biodiversity through an analysis of changes in the annual
60 occupancy of numerous invertebrate groups, bryophytes and lichens. The UK is relatively well
61 monitored in terms of national scale species' status and trends for some taxa^{15,16}. The farmland bird
62 index has declined by over 50% since 1970¹⁷, the abundance of specialist butterflies fell by 45% from
63 1976-2014¹⁸, and vascular plant communities have declined, largely in response to nitrogen
64 deposition¹⁹. Conversely, bat populations in Great Britain have generally shown stable or positive
65 trends since the late nineties²⁰. The estimation of these trends has been possible through the
66 standardised collection and analysis of abundance data. Equivalent knowledge is lacking for most
67 biodiversity, particularly invertebrates. However, due to the rich history of species observation and
68 recording across the UK that goes back many decades²¹, extensive occurrence data are available for

69 these groups in the form of biological records. A record is simply a report of a species by an observer
70 at a known time and place: most are collected opportunistically. These data have been under-utilised
71 because of concerns over biases resulting from the unstandardized nature of data collection²²⁻²⁴. Here,
72 we make use of recent advances in occupancy modelling techniques that address these concerns and
73 have enabled a wider range of occurrence record datasets to be analysed^{25,26}. We explore long-term
74 change in UK biodiversity through an analysis of the average annual occupancy of invertebrate groups,
75 bryophytes and lichens over a 45-year period. Occupancy is a measure of species range area: in this
76 study (and following others^{12,27,28}) occupancy refers to the proportion of 1km² grid cells in which a
77 species is present.

78 We analyse outputs from national scale models of annual occupancy spanning 1970-2015 for over 5,000
79 terrestrial and freshwater species from 31 groups including many insect families, other invertebrate
80 groups, bryophytes and lichens²⁹. We quantify trends in average occupancy across taxa and over time
81 and explore differences between common and rare species. We believe this represents the most
82 comprehensive assessment of its kind, with unprecedented scale and scope for a national biodiversity
83 assessment.

84 **Results**

85 **Multispecies trends in occupancy**

86 Our are comprised of occupancy estimates for 5,214 species in 31 taxonomic groups for each year from
87 1970-2015²⁹. These estimates are derived from hierarchical Bayesian occupancy-detection models for
88 each species and are based on 24,090,792 presence-only biological records. Multispecies trends are
89 summarised for four aggregate taxonomic and habitat-based groups. Freshwater species ($n=318$) are
90 considered separately from terrestrial species, since they are subject to different pressures. Terrestrial
91 species are aggregated into three groups reflecting major taxonomic boundaries: terrestrial insects
92 ($n=3,089$, hereafter referred to as insects), terrestrial non-insect invertebrates (mostly spiders, $n=538$,
93 hereafter “invertebrates”), and bryophytes & lichens ($n=1,269$).

94 Across all 5,214 species an index of overall occupancy, estimated as the geometric mean occupancy,
95 was 11% higher in 2015 compared with 1970 (95% credible interval: 9, 13%), contradicting the
96 narrative that declines are pervasive. However, there were substantial differences among major groups.
97 The most striking response was seen for the freshwater species. Although this group has experienced
98 little net change since 1970 (+7.2%: -3.3, +19%), an increase is observed following two decades of
99 consistent decline (Figure 1). At its lowest point, in 1994, freshwater species occupancy had declined
100 by 47% (-51, -42%) compared with levels in 1970. Terrestrial insects show a slight increase in
101 occupancy of 5.5% (+2.9, +8.1%) and bryophytes & lichen occupancy increased by 36% (+31, +42%).
102 The invertebrates are the only group to experience an overall decline in mean occupancy with a
103 reduction of 6.7% (-12, -1.6%).

104 Temporal variation in trends is clearly apparent when contrasting the net change in average occupancy
105 during the first (1970-1992) and second (1993-2015) halves of the series (Figure 2). Freshwater species
106 experienced an extreme change in trajectory, with the fastest declines exhibited across groups
107 experienced before 1992, and the fastest increase across groups, post-1992. Terrestrial insects and
108 invertebrates show opposite patterns with the former presenting an increase pre-1992 and a decline
109 post-1992, and the latter declining initially then stabilising. Bryophytes & lichens respond with a slow
110 increase pre-1992 then a more rapid increase post-1992. None of the five groups declined consistently
111 across the time period assessed: the freshwater and insect groups experienced a reversal in average trend
112 from the early and late parts of the time-series. This disparity across groups highlights the potential
113 variability in response to specific drivers of change and/or response to a variety of drivers.

114 We detected variation in the magnitude and timing of changes in the status of rare and common species
115 among groups (Figure 3). For both the insects and the bryophytes & lichens, the rare species showed
116 greater changes in occurrence than the common species. Conversely, the pattern of change of the
117 common Freshwater species indicates an earlier start to the recovery phase than for rare species.
118 Invertebrates present no difference in response between rare and common species implying that the
119 composition of invertebrate communities has changed less than in the other groups. Differing responses
120 between rare and common species observed for some groups is indicative of species turnover in local
121 communities with rare species becoming more common or vice versa.

122 There is considerable heterogeneity within the four groups, with some taxa facing substantial declines
123 not apparent from the average group level change (Figure 4), this is particularly evident for the insect
124 group. Most taxa in the freshwater group show the U-shaped trajectory of the average response. The
125 overall decline of the invertebrates is mainly driven by spiders during the early period, and by terrestrial
126 molluscs more recently. Bryophytes & lichens increase overall, but the timing of these increases differ.
127 Across all 31 taxonomic groups, ten increased in mean occupancy (95% credible intervals for the year
128 2015 do not span 100) and five decreased (see Table S1 and Extended Data Figure 1 for more details).

129 Aggregating species level change into indicators of average occupancy over time hides the variation
130 among species. Within any group there will be winners and losers whose response is more extreme
131 than that of the average³⁰. Analysis of the annual growth rates (year to year change) in occupancy of
132 individual species reveals that although the mean change in occupancy is an increase of 11%, there are
133 species that have undergone substantial declines (some of which started out relatively common), as well
134 as initially rare species that have increased dramatically over time (Figure 5). There is little correlation
135 between average occupancy and average growth rate for any of the four major groups (Pearson's
136 correlation coefficient: Freshwater = -0.078, Insects = 0.002, Invertebrates = -0.061 and Bryophytes &
137 lichens = -0.0001). Although most species can be found around the zero line, there are large numbers
138 of species whose distribution changed dramatically. The lowest decile (n=529) of species' growth rates

139 is -2.1%, i.e. 10% (529) of species declined by at least 2.1% each year. Across the full range of 46 years
140 in our dataset, this corresponds to a loss of 62% of previously occupied grid cells. The upper decile is
141 2.4%, i.e. 10% of species increased by at least this amount each year, corresponding to a tripling in
142 distribution over 46 years. Determining drivers of change and those species most likely to exhibit strong
143 responses will aid in mitigation of future losses.

144 **Discussion**

145 Our analysis of changes in occupancy for over 5,000 UK species has shown that only one of the four
146 aggregate groups, the invertebrates, presents a decline in average occupancy. Based on widely reported
147 declines in the abundance of UK birds³¹ and butterflies³, and for other taxa globally^{2,32}, one might expect
148 to see declines in occupancy, but our results confound this expectation. Not only is the overall net
149 change positive, the direction of change is different among groups and there is enormous variation
150 among taxa in the temporal pattern of change and the relative fates of rare and common species. By
151 broadening the taxonomic scope of investigation to these lesser-known groups, our results challenge
152 the received wisdom that all biodiversity change is loss, and it is both pervasive and unalterable.

153 The increasing trajectories among bryophytes & lichens (since 1970) and the freshwater group (since
154 1994) both suggest a beneficial impact of environmental regulations and consequent management
155 changes in reversing biodiversity declines. Bryophytes and lichens are known to be particularly
156 sensitive to acidic pollutants such as sulphur dioxide³³, and the atmospheric concentrations of these
157 chemicals have been declining since the first Clean Air Act of 1956. Overall, freshwater species
158 experienced substantial declines up until the mid-nineties followed by a recovery to 1970 levels. This
159 U-shaped trajectory is replicated for four of the six freshwater taxa, suggesting a common response to
160 a single driver. It is notable that the lowest mean occupancy for the freshwater group follows shortly
161 after the introduction of the European Urban Wastewater Treatment Directive in 1991, and the step
162 change in regulation of the water industry after privatization in 1989³⁴. Improvements in water quality
163 have been linked to increases in family level richness of freshwater invertebrates in Great Britain from
164 the early nineties onward^{35,36} and historically at sampling locations in England³⁷. The recent increases
165 we report must be seen in the context of much larger declines that probably occurred over two centuries
166 since the industrial revolution. This makes it hard to interpret the relative trajectories of rare and
167 common species, or the apparent stasis in freshwater occupancy since 2005. Nonetheless, the recoveries
168 in bryophytes, lichens and freshwater species, concomitant with improvements in air and water quality
169 over recent decades, contributes to a growing trend of optimistic narratives in debates about biodiversity
170 conservation^{9,38}.

171 Caveats about declines prior to 1970 also apply to the other major groups under consideration. It is
172 well-established that major transformations of the UK landscape occurred during the middle parts of
173 the 20th century^{39,40} so care is needed to avoid the pitfalls of shifting baseline syndrome^{41,42}. Values

174 seen in 1970 must not be seen as a target to be reached, since it is likely that levels in 1970 were also
175 considerably lower than earlier in the century.

176 It should be noted that both recent colonist species and non-native species (such as the Harlequin
177 ladybird) are included in the set of species analysed here, since they also contribute to UK biodiversity
178 change⁴³. However, their low numbers (56 species, just over 1% of the total - see Methods for a
179 breakdown) result in very little influence on the multispecies trajectories presented here.

180 Our results demonstrate the insights that can be gathered from careful analysis of presence-only
181 occurrence records. However, they raise questions about how trends in occupancy should be interpreted
182 in the context of more widely-used metrics, such as changes in abundance², species richness⁴⁴,
183 biomass^{10,45} or other measures of range size^{46,47}. For example, changes in total abundance⁴⁸, in total
184 biomass¹⁰ or in average species' abundance^{3,31} measure similar, but subtly different, facets of
185 biodiversity. Here, our focus is on the average change across species (as in biodiversity indicators), so
186 we assess average occupancy across species and changes therein. In general, we would expect trends
187 in average occupancy to under-estimate trends in average abundance, but that the two metrics would be
188 closely correlated⁴⁹⁻⁵¹. Indeed, van Strien *et al*, when assessing trends in both the occupancy and
189 abundance of butterflies in the Netherlands observed greater changes in average abundance than in
190 average occupancy, but both metrics present an overall negative trend⁵². Similarly, species richness
191 and occupancy can be thought of as alternative ways of summarizing a three dimensional space-time-
192 species data cube in which the cells of the cube represent the binary presence-absence state^{53,54}.
193 Typically, if average occupancy goes up, average richness per grid cell will also go up, so trends in
194 richness and occupancy should be closely correlated.

195 This study takes us a step closer to understanding the status of UK biodiversity by exploring patterns
196 of change for groups of species that have previously been neglected in large-scale studies of change. It
197 is clear that occupancy is a valuable tool for assessing patterns over time when abundance data are not
198 available. Over time, available models and required computation time will improve, enabling the wider
199 application of occupancy modelling with models developed specifically to suit each dataset rather than
200 the one-size-fits-all approach taken to generate the estimates used here. Although more bespoke
201 modelling approaches could deliver greater insights when exploring change for individual species, we
202 believe this approach is a reasonable trade-off since we are interested in aggregated trends. However,
203 this is currently the only and best information available for most of these species groups. Importantly,
204 this work presents just one facet in the multifaceted nature of biodiversity change⁵⁵.

205

206

207 **Methods:**

208 Details of the methods used in the analyses presented here are described below. These analyses can be
 209 recreated using the original data through the associated R package *UKBiodiversity*. This R package is
 210 available from GitHub (<https://github.com/CharlieOuthwaite/UKBiodiversity>). The package vignette
 211 contains detailed instructions for reproducing each of the statistics and figures presented here.

212 **Data**

213 A species occurrence dataset, as presented by Outhwaite *et al*²⁹, was used to assess annual species
 214 occupancy and determine estimates of annual growth rate. This dataset includes 1,000 samples from
 215 the posterior distribution of occupancy estimates for 5,293 species from 1970 to 2015. These data are
 216 freely available from the Natural Environment Research Council (NERC) Environmental Information
 217 Data Centre (EIDC, <https://doi.org/10.5285/0ec7e549-57d4-4e2d-b2d3-2199e1578d84>)²⁹. An
 218 associated Shiny app (<https://shiny-apps.ceh.ac.uk/speciesplotviewer/>) can be used to view
 219 occupancy and detection plots for individual species, although we emphasise that the models developed
 220 here may not be optimal for every individual species considered: the plots should not be used
 221 uncritically for single-species assessments, therefore. These estimates are derived from occurrence
 222 records analysed using a Bayesian occupancy modelling framework based on that of Outhwaite *et al*.²⁵
 223 The model used is a hierarchical model that separates occupancy and detection to allow for the
 224 accounting of imperfect detection. Imperfect detection and other biases are common in occurrence
 225 record datasets such as those used by Outhwaite *et al*²⁹, however occupancy modelling has been shown
 226 to be the most appropriate method for analysing this form of data²⁶. The model used to generate the
 227 occupancy estimates analysed here is made up of the following submodels.

228 The state model describes the true occupancy state, z_{it} , of a site i in year t (equations (1) and (2)). z_{it}
 229 will be 1 when a site is occupied and 0 if not occupied. The true occupancy, z_{it} , then takes a Bernoulli
 230 distribution:

$$231 \quad z_{it} \sim \text{Bernoulli}(\psi_{it}), \quad (1)$$

232 The logit of the probability of occurrence, ψ_{it} , varies with both year and site:

$$233 \quad \text{logit}(\psi_{it}) = \log\left(\frac{\psi_{it}}{1-\psi_{it}}\right) = b_{tr(i)} + u_i, \quad (2)$$

234 $b_{tr(i)}$ is the year effect for year t in region r in which site i is found. u_i is the site effect.

235 The observation model describes the data collection process. It is conditional on the true occupancy
 236 state z_{it} . p_{iv} is the probability that a species will be observed on a single visit, given the species is
 237 present at that site. The observation, y_{iv} , is then drawn from a Bernoulli distribution conditional on the
 238 true occupancy state:

$$239 \quad y_{iv}|z_{it} \sim \text{Bernoulli}(p_{iv}z_{it}) \quad (3)$$

240 Variation in detection probabilities p_{iv} , per visit are described as:

241
$$\text{logit}(p_{itv}) = \log\left(\frac{p_{itv}}{1-p_{itv}}\right) = a_t + \beta_1 * \text{datatype2}_{itv} + \beta_2 * \text{datatype3}_{itv}, \quad (4)$$

242 where β_1 and β_2 estimate differences in $\text{logit}(p_{itv})$ for a list length of 2-3 (datatype2) and of 4+ (datatype
243 3) respectively, relative to a list length of one and a_t is a year effect.

244 Full details of the model used can be found in the data paper associated with the species occurrence
245 dataset²⁹. All species included in the species occurrence dataset are used here except for the Rove
246 Beetles (79 species). The Rove Beetles only have data for 1980 onwards, since the indicators we present
247 start at 1970 it was decided that this group would be removed to maintain a simple indicator method.
248 We therefore assess changes in occupancy over time for 5,214 species. The dataset contains derived
249 estimates of annual occupancy, with appropriate measures of uncertainty, for species with at least 50
250 records (see ²⁹ for more detail). Although this is very few records across the 45-year time period,
251 increasing this threshold to 200 records per species did not materially change the trajectories of the
252 aggregate group level change observed in Figure 1 (see Extended Data Figure 2 in the). A higher
253 threshold was therefore not deemed necessary.

254 We conducted a posterior predictive checking exercise to assess whether our models are appropriately
255 parameterized and not over- or under-fit (see below). Since the inferences in the paper are about trends
256 in large multispecies taxa, we calculate summaries for groups of species rather than for individual
257 species.

258 **Species grouping**

259 Species were aggregated into four major groups. Freshwater species were analysed separately, and the
260 terrestrial species were split into three groups (Table S2). Freshwater molluscs were separated from
261 terrestrial molluscs based on expert opinion and web-based searches. Each of the 31 taxonomic groups
262 considered here represents either a single family (e.g. ants, family Formicidae), a selection of families
263 (e.g. Plant Bugs) or a grouping of higher taxonomic rank (e.g. caddisflies, order Trichoptera). These
264 groups represent the sets of species recorded by separate recording schemes within the UK (more
265 information on these schemes can be found here: <https://www.brc.ac.uk/recording-schemes>).

266 Recent colonists and non-native species have not been excluded from this study. Due to their small
267 number within each of the four aggregate groups their influence on the overall patterns of change in
268 this study is minimal (Table S3). Most of the species known to be recent colonists to the UK that are
269 included in this study are moths ($n = 32$). Species were identified from two lists: first, a list of recent
270 colonists into the UK established from the literature and a list of established non-native species derived
271 from the GB Non-native Species Secretariat Information Portal species register.

272 **Composite trends**

273 The composite multispecies indicators (as shown in Figures 1, 3 and 4) are calculated as the geometric
 274 mean across species⁵⁶. To generate these indicators, we used the posterior samples of the occupancy
 275 estimates for each species in each year provided within the “POSTERIOR_SAMPLES” folder of the
 276 data source²⁹. These consist of 1000 samples describing the proportion of occupied sites per species
 277 per year. For each group of species (per taxa or per aggregate group), the 1000 samples for each species
 278 within that group or taxon were assessed. For each group (or taxon), the multispecies structure was
 279 represented in the following way:

$$280 \quad Y_{ist} = \alpha_t + \beta_{st} + \varepsilon_{ist} \quad (t = 1, \dots, T; s = 1, \dots, S; i = 1, \dots, n), \quad (5)$$

281 where T is the total number of years considered, S is the total number of species, n (=1000 here) is the
 282 number of posterior samples and Y_{ist} is the logarithm of the i th posterior occupancy sample for species
 283 s in year t . In this representation, α_t denotes the posterior index of overall log-occupancy in year t ; β_{st}
 284 is an adjustment representing the extent to which species s differs from this overall value; and the $\{\varepsilon_{ist}\}$
 285 are independent random variables, each with expectation zero over the posterior distribution,
 286 representing the posterior variation for each species:year combination. To ensure that the representation
 287 (5) is unique and that α_t has the desired interpretation, the constraint $\sum_{s=1}^S \beta_{st} = 0$ is imposed for each
 288 year. Without this constraint there are $T+TS$ coefficients (the $\{\alpha_t\}$ and $\{\beta_{st}\}$ in equation (5)), but only
 289 TS species:year combinations in the posterior dataset: with T constraints in total on the $\{\beta_{st}\}$, the
 290 redundancy is removed.

291 Define $\bar{Y}_{it} = S^{-1} \sum_{s=1}^S Y_{ist}$, the mean of the i th posterior samples across all species at time t . Under the
 292 assumption that the posterior occupancy probabilities for different species are independent, the
 293 quantities $\{\bar{Y}_{it}: i = 1, \dots, n\}$ are themselves samples from the posterior distribution of overall log-
 294 occupancy for year t (the independence assumption is needed to justify combining posterior samples
 295 across species). Each has expected value

$$296 \quad \mathbb{E}(\bar{Y}_{it}) = S^{-1} \mathbb{E}(\sum_{s=1}^S Y_{ist}) = S^{-1} \mathbb{E}[\sum_{s=1}^S (\alpha_t + \beta_{st} + \varepsilon_{ist})] = \alpha_t, \quad (6)$$

297 the remaining terms vanishing because $\sum_{s=1}^S \beta_{st} = \mathbb{E}(\varepsilon_{ist}) = 0$. Therefore, if n is large then the mean
 298 of the $\{\bar{Y}_{it}: i = 1, \dots, n\}$ will be close to α_t , the desired index of overall log-occupancy. Thus, $e^{\bar{Y}_{it}}$
 299 corresponds to the geometric mean occupancy, which we present in Figure 1 and 4, after rescaling to
 300 start at 100 in 1970, with the mean and 95% quantiles taken to summarise the uncertainty of this index.
 301 To determine whether the patterns observed in Figure 1 were due to specific species responses within
 302 these groups rather than random variation, the indicators were all recalculated for alternative datasets
 303 produced by randomly reassigning species to major groups in such a way that each group contained the
 304 same number of species as in reality: this reassignment, which is carried out in the spirit of a permutation
 305 test (ref⁵⁷ Section 3.3) ensures that any inter-group differences in the alternative datasets can only be
 306 due to random variation. Results, such as those in Extended Data Figure 3, do not show the kinds of

307 patterns that are observed in Figure 1: these patterns therefore represent genuine inter-group differences
308 rather than random inter-species variation.

309 Indices presenting changes in rarity and commonness of species over time (Figure 3) were calculated
310 in a similar way. Specifically, rather than estimating the geometric mean occupancy $\{\bar{Y}_{it}\}$ across species
311 posterior samples within a major group, we estimate the quantiles $\{Q_{it}\}$ corresponding to rare species
312 (25th percentile) and common species (75th percentile). Figure 3 then summarises the posterior
313 distributions $\{100e^{Q_{it}-Q_{i1}}\}$, for each of these quantiles.

314 Percentage change in occupancy of all species and aggregate groups, presented in the main text, was
315 calculated using the geometric mean occupancies for the first, \bar{Y}_{i1} , and last years, \bar{Y}_{iT} , (1970 and 2015
316 respectively):

$$317 \quad \delta_i = 100(e^{\bar{Y}_{iT}} - e^{\bar{Y}_{i1}})/e^{\bar{Y}_{i1}}, \quad (7)$$

318 Similarly, annual growth rates, λ_i , for each species, provided within the data source, as:

$$319 \quad \lambda_{is} = 100 \left(\left(\frac{Y_{isT}}{Y_{is1}} \right)^{\frac{1}{T}} - 1 \right) \quad (8)$$

320 For the calculation of species' growth rates, we used only the first (t=1) and last (t=T) years in which
321 the species was recorded, in order to avoid any bias due to the potential information in the priors²⁵.

322

323 **Sensitivity of the indicators to the number of records of a species**

324 The dataset of annual occupancy estimates for UK species that formed the basis of this analysis included
325 modelled outputs for species which had 50 records or more within the raw dataset (see ref⁵⁸ for more
326 details). This is a very low number of records across the dataset that encompasses the years 1970 to
327 2015. To ensure that species with few records were not having a large influence on the overall trends
328 and patterns of change over time, we recalculated the major group indicators presented in Figure 1 of
329 the main text but used higher thresholds of the number of records of a species (Extended Data Figure
330 2). Overall, higher thresholds (including 75, 100, 150 and 200 records minimum per species) did not
331 have a major effect on the patterns of change over time observed in Figure 1. Trends differed slightly,
332 such as for the Bryophytes & lichens in some instances, but no major differences or changes in direction
333 were seen.

334 **Variability within major group level indicators**

335 Considering that the major group indicators present the average change across hundreds to thousands
336 of species, it is likely that the variation across species will be high. In order to determine whether the
337 patterns observed were a result of this random variation or were representing common responses across
338 species we recreated the indicators presented in Figure 1 of the main text but randomised the species

339 within each major group. So, for each of the four major groups the same total number of species within
340 it was maintained, but the species identified were randomly selected from the complete species pool.
341 This species randomisation and indicator generation was carried out 12 times to see if the patterns of
342 change observed could be recreated from the randomly selected set of species. Extended Data Figure
343 3 shows the analogue of Figure 1 in the main text, for each of the 12 alternative data sets obtained by
344 randomisation in this way. For most of them, all four groups show very similar trends in occupancy that
345 are similar to the overall increase of 11% reported in the main text: the fifth alternative dataset shows a
346 separation into two pairs of groups, but none of these alternative datasets shows structures similar to
347 those presented in Figure 1. This provides reassurance that those structures are indeed associated with
348 genuine inter-group differences and cannot be attributed merely to random inter-species variation.

349 **Posterior predictive checking**

350 This section presents the results of some diagnostics that have been used to check our models' ability
351 to reproduce selected features of the observations as aggregated over species groups: these checks have
352 been carried out to provide some reassurance that the models are sufficiently flexible and realistic to
353 capture the structures seen in the data, and hence to support the use of the models to make statements
354 about long-term changes in occupancy.

355 Posterior predictive checking is a Bayesian technique that is designed to assess how well a model
356 reproduces features of a data set⁵⁹. The basic principle is, having fitted a model to a set of observations,
357 y , to generate from the model a corresponding data vector, y_{rep} . If the data is appropriately parameterized
358 then y and y_{rep} should be similar in some sense.

359 In the case of an occupancy-detection model, the observations for each species' model is a vector
360 containing an entry 0 or 1 for each relevant visit in the database — 1 if the species was reported, 0
361 otherwise. 'Similarity' is defined by comparing relevant properties of the observed and simulated data
362 vectors.

363 In our models, the observed detections y are assumed to be generated probabilistically and therefore the
364 observed summary $T(y)$ is also drawn from some probability distribution: formally, it's the realised
365 value of a random variable $T(Y)$, where Y is a random vector whose joint distribution is specified by the
366 model. We don't know exactly what this distribution is because, even if the model structure is correct,
367 we don't know the parameter values exactly. However, we do have a posterior distribution for the
368 parameters. If we draw repeated samples from this posterior distribution and, for each sample, use the
369 model to (a) generate a synthetic data set y_{rep} (b) calculate the corresponding summary $T(y_{rep})$, then we
370 can build up a collection of samples from a distribution of $T(\cdot)$ that accounts both for the randomness
371 in the model and for the parameter uncertainty. Such a distribution is called a "posterior predictive
372 distribution". The observed summary $T(y)$ can then be compared with the posterior predictive
373 distribution as a check on model performance.

374 In the present context, for each species the replications y_{rep} need to be generated to mimic as closely as
375 possible the process that generated the data under the model: the same sites, same numbers of visits and
376 associated list lengths. Two separate summary measures $T(y)$ were calculated for each group of species.
377 The first was the overall proportion of sites with a detection, averaged over all species and years; and
378 the second was the variance in the annual mean proportion of detections for the group (see below). This
379 choice enables us to check the model's ability to reproduce features at the same level of group
380 aggregation as the main analyses in the paper: moreover, the variance in annual mean detections is a
381 measure of interannual variation which is related to the indices of change in the paper. Of course, it is
382 not possible to compare the modelled occupancies with observations, because occupancy is not
383 observed; since detection is conditional on occupancy however, we may have some confidence that
384 models represent properties of the aggregated occupancies reasonably well if they can represent the
385 corresponding properties of aggregated detections. We implemented the following protocol for each
386 taxonomic group:

- 387 1. For each of V visits within each species' model, extract 99 samples from the posterior
388 distribution of the probability that an observation was made on that visit. In practical terms, this
389 probability is the product of the true (unknown) occupancy, z_{it} , and the detection probability,
390 p_{itv} (see equation 4 in Outhwaite *et al* 2019).
- 391 2. Use each of the 99 sets of probabilities to sample a vector of potential observations under the
392 model, by treating each visit as a potential Bernoulli trial. These vectors are 99 realisations of
393 y_{rep} .
- 394 3. For each realisation y_{rep} and for each year (1970-2015), calculate the annual proportion of sites
395 in which the species was recorded: denote this proportion, for species s and year t , by $T_{st}(y_{rep})$.
- 396 4. Calculate $T_{gt}(y_{rep})$ for each replicate dataset as the mean of $T_{st}(y_{rep})$ across species in each
397 taxonomic group.
- 398 5. Calculate the mean across years as $T_{gm}(y_{rep})$ for each replicate dataset.
- 399 6. Calculate $T_{gv}(y_{rep})$ as the variance across years in $T_{gt}(y_{rep})$ for each replicate dataset.
- 400 7. Calculate the observed mean proportion of sites with records, $T_{gm}(y)$, and the variance across
401 years $T_{gv}(y)$ for each replicate dataset.
- 402 8. Summarise the distribution of $T_{gm}(y)$ and $T_{gv}(y)$ as the mean and 95% credible intervals to
403 demonstrate the variation in summary measures that can reasonably be expected under the
404 model.

405 Computational limitations made this exercise unfeasible for four groups (Bryophytes, Dragonflies,
406 Moths and Lichens). Molluscs are treated as a single group for this exercise since models were run as a
407 complete group, but species were split into freshwater and terrestrial for the main analysis.

408 The mean proportion of sites with records is very well predicted on average, although rather uncertain
409 in many taxonomic groups (Extended Data Figure 4).

410 The interannual variability is estimated very precisely by the model for most species (posterior
411 predictive intervals are narrow, see Extended Data Figure 5), and shows excellent agreement with the
412 observations for almost all taxonomic groups. There are a few taxa for which the observed value does
413 not fall within the range of the posterior predictive interval, although in absolute terms the discrepancies
414 are sufficiently small as not to compromise the main messages in the paper: the explanation for these
415 discrepancies is either that the model is slightly biased for these species, or that the predictive
416 uncertainties have been underestimated so that the intervals are slightly too narrow.

417 **Author Contributions:**

418 NJBI, BC and RDG conceived the study. CLO extracted and analysed the data and drafted the
419 manuscript. REC determined the composite indicator method. All authors contributed to the writing
420 and editing of the manuscript.

421 **Data Availability:**

422 The dataset analysed as a part of this study is publicly available from The Environmental Information
423 Data Centre (EIDC) [30]. Additional information is supplied within the associated R package
424 *UKBiodiversity* which is available from GitHub
425 (<https://github.com/CharlieOuthwaite/UKBiodiversity>) and Data Descriptor [29].

426 **Code Availability:**

427 The code used to analyse the data is available from GitHub within an R package: *UKBiodiversity*
428 (<https://github.com/CharlieOuthwaite/UKBiodiversity>).

429 **Competing interests:**

430 The authors declare no competing interests.

431 **Acknowledgements:**

432 We would like to acknowledge the input of the recording schemes and societies that contributed data to
433 the dataset underlying this study and for their input in interpreting group level change. These schemes
434 are: the Aquatic Heteroptera Recording Scheme, the Bees, Wasps and Ants Recording Society, the
435 British Arachnological Society, Spider Recording Scheme, the British Bryological Society, the British
436 Dragonfly Society: Dragonfly Recording Network, the British Lichen Society, the British Myriapod
437 and Isopod Group: Centipede Recording Scheme, British Myriapod and Isopod Group: Millipede
438 Recording Scheme, the Chrysomelidae Recording Scheme, the Conchological Society of Great Britain
439 and Ireland, the Dipterists Forum: Cranefly Recording Scheme, the Dipterists Forum: Empididae,
440 Hybotidae & Dolichopodidae Recording Scheme, the Dipterists Forum: Fungus Gnat Recording
441 Scheme, the Dipterists Forum: Hoverfly Recording Scheme, the Gelechiid Recording Scheme, the

442 Grasshoppers and Related Insects Recording Scheme, the Ground Beetle Recording Scheme, the

588 **Figure Legends:**

589

590 **Figure 1: Composite estimates of average annual occupancy of four groups of species.** Values are
591 scaled to 100 in 1970. Coloured lines show the average response as the geometric mean occupancy
592 and the shaded area represents the 95% credible intervals of the posterior distribution of the geometric
593 mean. *n* denotes the number of species contributing to each group. Uncertainty for each year is
594 expressed relative to the 1970 baseline. Change metrics reported in the text account for uncertainty in
595 both the first and last year of the series.

596 **Figure 2: Absolute change in geometric mean occupancy during the first (1970–1992) and second**
597 **(1993–2015) halves of the time series for each major group.** Each boxplot represents the posterior
598 distribution of overall absolute change in occupancy within the group, over the relevant time period.
599 The centre of the boxplot represents the median of the distribution with lower and upper hinges
600 corresponding to the 25th and 75th percentiles. The whiskers represent the 95% credible intervals.

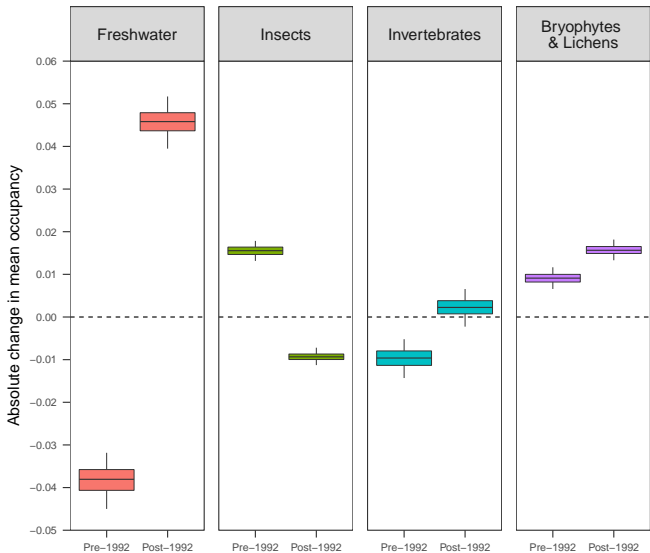

601 **Figure 3: Composite estimates of two quantiles of annual occupancy across the four major groups.**
602 Two quantiles were chosen to represent varying levels of occupancy: common or widespread (0.75 -

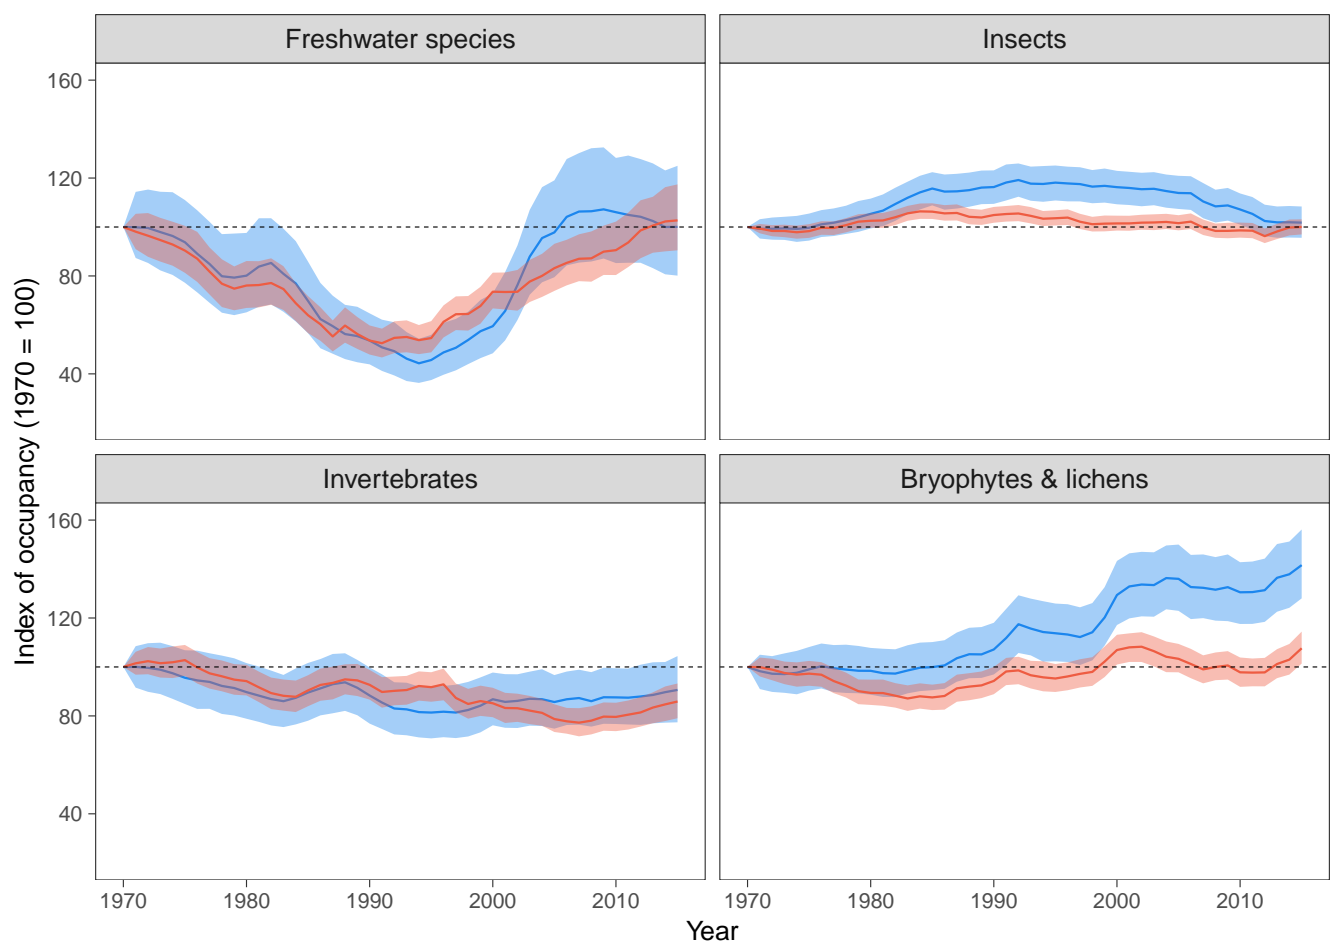

603 green) and rare or localised occupancy (0.25 - purple). These quantiles of occupancy were assessed
604 each year to show how rareness and commonness changed over time for each group. In each case, the
605 shaded area delimits the 95% credible intervals.

606 **Figure 4: Composite estimates of average annual occupancy of each taxonomic subgroup.** Taxa
607 within the freshwater and insect groups are displayed across multiple panels to aid visibility. Values
608 are scaled to 100 in 1970. Coloured lines show the average response as the geometric mean occupancy
609 and the shaded area represents the 95% credible intervals of the posterior distribution of annual
610 occupancy estimates. The width of the credible intervals is a function of the number of species within
611 the group. Note that y-axes vary.

612 **Figure 5: Heat map of comparison between each species' average occupancy estimate across the**
613 **entire period and its' average annual growth rate (expressed as a percentage of the initial occupancy,**
614 **see Methods) for each of the four major groups.** Brighter shades represent a greater number of species
615 within that hexagon. The greater the average occupancy value on the y- axis, the more common the
616 species. Hexagons to the left of the vertical, dashed line (growth rate = 0) include species with a
617 negative annual growth rate, those on the right have a positive annual growth rate. Six extreme positive
618 growth rates are not shown.
