#### Abstract

We present deep optical spectra of 23 galactic planetary nebulae, which are analysed in conjunction with archival infrared and ultraviolet spectra. We derive nebular electron temperatures based on standard collisionally excited line (CEL) diagnostics as well as the hydrogen Balmer jump and find that, as expected, the Balmer jump almost always yields a lower temperature than the $\left[\mathrm{O}_{\mathrm{III}}\right]$ nebular-to-auroral line ratio. We also make use of the weak temperature dependence of helium and $\mathrm{O}_{\text {II }}$ recombination line ratios to further investigate the temperature structure of the sample nebulae. We find that, in almost every case, the derived temperatures follow the relation $T_{\mathrm{e}}(\mathrm{CEL}) \geqslant T_{\mathrm{e}}(\mathrm{BJ}) \geqslant T_{\mathrm{e}}\left(\mathrm{He}_{\mathrm{I}}\right) \geqslant T_{\mathrm{e}}(\mathrm{O}$ II $)$, which is the relation predicted by two-component nebular models in which one component is cold and hydrogen-deficient. $T_{\mathrm{e}}\left(\mathrm{O}_{\text {II }}\right)$ may be as low as a few hundred Kelvin, in line with the low temperatures found for the hydrogen-deficient knots of Abell 30 by Wesson, Liu and Barlow.

Elemental abundances are derived for the sample nebulae from both CELs and optical recombination lines (ORLs). ORL abundances are higher than CEL abundances in every case, by factors ranging from 1.5 to 12 . Five objects with $\mathrm{O}^{2+}$ abundance discrepancy factors greater than 5 are found. DdDm 1 and $\mathrm{Vy} 2-2$ are both found to have a very large abundance discrepancy factor of 11.8.

We consider the possible explanations for the observed discrepancies. From the observed differences between $T_{\mathrm{e}}\left(\mathrm{O}_{\mathrm{III}}\right)$ and $T_{\mathrm{e}}(\mathrm{BJ})$, we find that temperature fluctuations cannot resolve the abundance discrepancies in 22 of the 23 sample nebulae, implying some additional mechanism for enhancing ORL emission. In the one ambiguous case, the good agreement between abundances derived from temperature-insensitive infrared lines and temperature-sensitive optical lines also points away from temperature fluctuations being present. The observed recombination line temperatures, the large abundance discrepancies and the generally good agreement between infrared and optical CEL abundances all suggest instead the existence of a cold hydrogen-deficient component within the 'normal' nebular gas. The origin of this component is as yet unknown.

Key words: ISM: abundances - planetary nebulae: general.

## 1 INTRODUCTION

A long-standing problem in nebular astrophysics is that abundances derived from optical recombination lines (ORLs) are universally higher than those derived from collisionally excited lines (CELs). The discrepancies observed are typically a factor of $2-3$, but exceed a factor of 5 in approximately 5 per cent of planetary nebulae. The most extreme cases known are NGC 1501, Hf 2-2 and Abell 30, for which the abundance discrepancies for $\mathrm{O}^{2+}$ are factors of 32,84
*E-mail: mjb@star.ucl.ac.uk
and 700, respectively (Liu 2003; Wesson et al. 2003; Ercolano et al. 2004). Closely linked to this problem is the discrepancy whereby electron temperatures derived from the hydrogen Balmer jump are systematically lower than those derived from [ $\mathrm{O}_{\mathrm{III}}$ ] forbidden lines.

Many theories have been advanced to resolve these discrepancies. Peimbert (1967) showed that in a thermally inhomogeneous nebula, CEL emission would be weighted towards the hotter regions, while recombination line emission would be weighted towards cooler regions. The temperatures derived from CEL diagnostics would be overestimated, and so CEL abundances would be underestimated. In this case, ORL abundances should be more reliable than CEL abundances.

However, while this scenario can potentially resolve small discrepancies, up to a factor of 3 or so, the discovery in recent years of more extreme objects such as NGC 7009 (Liu et al. 1995), NGC 6153 (Liu et al. 2000), M 1-42 and M2-36 (Liu et al. 2001), with discrepancies exceeding a factor of 5 , has shown that temperature fluctuations cannot be the sole cause of the abundance discrepancies in the more extreme cases. Even in nebulae with more moderate discrepancies such as NGC 6543, detailed analysis by Wesson \& Liu (2004) showed that the temperature fluctuations present were too small to resolve the ORL/CEL abundance discrepancy factor (adf) of 3 .

Infrared (IR) fine structure lines have low excitation temperatures ( $\leqslant 1000 \mathrm{~K}$ ) compared to typical nebular temperatures, and so should be insensitive to temperature fluctuations. Therefore, if temperature fluctuations were the cause of the discrepancy, the IR lines would be expected to yield similar abundances to ORLs. However, this is shown not to be the case for many nebulae (Liu et al. 2000, 2001; Tsamis 2002; Tsamis et al. 2004).

Instead, hydrogen-deficient material present in nebulae seems to offer a more viable explanation of the observed temperature and abundance discrepancies (Liu et al. 2000; Péquignot et al. 2003). Such material would be strongly cooled by IR emission from heavy element ions, and thus CEL emission would be strongly suppressed, while ORL emission would be enhanced due to the inverse power-law temperature dependence of ORL emissivities. In this case, abundances derived from CELs would be close to the average abundance of the whole nebula, as the hot component would contain the majority of the nebular material, while ORL abundances would apply to the cold H-deficient knots. Wesson et al. (2003) showed that very cold ionized material exists in the known H deficient knots of Abell 30, with subsequent photoionization modelling by Ercolano et al. (2003) further demonstrating the physical plausibility of the existence of ionized material at temperatures of $<2000 \mathrm{~K}$.
In this paper we present observations and analysis of new optical and archival IR and ultraviolet spectra of a sample of 23 planetary nebulae. Physical conditions are determined from standard forbidden diagnostics, as well as from the hydrogen recombination spectrum and recombination lines of heavy elements. Abundances are determined from both CELs and ORLs. It is shown that discrepancies between ORL and CEL abundances are present in all nebulae analysed, with values of $\operatorname{adf}\left(\mathrm{O}^{2+}\right)\left[=\left(\mathrm{O}^{2+} / \mathrm{H}^{+}\right)_{\mathrm{ORL}} /\left(\mathrm{O}^{2+} / \mathrm{H}^{+}\right)_{\mathrm{CEL}}\right]$ ranging from 1.5 to 12 . Possible explanations for the discrepancy are considered, and it is shown that, in almost every case, temperature fluctuations described by the formalism of Peimbert (1967) are unable to resolve the observed abundance discrepancies. Instead, there is strong evidence to suggest that cold H -deficient regions are present in most if not all planetary nebulae.

## 2 OBSERVATIONS

### 2.1 Optical spectra

The optical spectra for the planetary nebulae analysed in this section were obtained using the Intermediate Dispersion Spectrograph (IDS) on the $2.5-\mathrm{m}$ Isaac Newton Telescope at the Observatorio del Roque de los Muchachos, on La Palma, Spain, between 2001 August 1 and 5. Spectra were taken covering two wavelength ranges. The R1200B grating was used to cover the range 3500-5000 At a resolution of $0.95 \AA$ FWHM, thus covering most important ORLs of $\mathrm{C}^{2+}, \mathrm{C}^{3+}, \mathrm{N}^{2+}, \mathrm{N}^{3+}, \mathrm{O}^{2+}$ and $\mathrm{Ne}^{2+}$, as well as the hydrogen

Balmer jump, at high spectral resolution. The R300V grating, in conjunction with a GG385 order-sorting filter, was used to cover wavelengths from $3800-7700 \AA$ at a resolution of $4.0 \AA$ FWHM. These low-resolution spectra were used to derive the logarithmic extinction at $\mathrm{H} \beta, c(\mathrm{H} \beta)$, from the observed ratio of $\mathrm{H} \alpha / \mathrm{H} \beta$, and temperatures and densities from forbidden line diagnostics. A slit 1 arcsec wide and $4 \operatorname{arcmin}$ long was used for all observations. A $\log$ of the observations is given in Table 1. This table also contains published total $\mathrm{H} \beta$ fluxes from Cahn, Kaler \& Stanghellini (1992), angular dimensions of the nebulae from the Strasbourg-European Southern Observatory (ESO) Catalogue (Acker et al. 1992) and the values of $c(\mathrm{H} \beta)$ derived in Section 3.1.

### 2.1.1 Data reduction

The two-dimensional image frames were reduced using the LONG92 package within MIDAS, and also IRAF. Using MIDAS, they were biassubtracted, flat-fielded, cleaned of cosmic rays and wavelength calibrated using a $\mathrm{Cu}-\mathrm{Ar}$ calibration lamp. The spectra were flux calibrated using wide-slit ( 6 arcsec) observations of the standard stars Feige $110, \mathrm{HZ} 44$ and BD+28 4211. IRAF was used to fit the observed flux distributions with high-order spline functions.
In all cases, the angular diameter of the nebula was less than our slit length and so suitable sky windows could be selected on either side of the nebular emission. The sky background was fitted in the direction of the slit by a second-order polynomial and subtracted from the two-dimensional image frame. Atmospheric extinction was corrected for using the published mean atmospheric extinction curve for La Palma (King 1985). Nebular emission was then summed over the observed spatial extent along the slit of the $\mathrm{H} \beta$ line, and the resulting one-dimensional spectra were normalized such that $F(\mathrm{H} \beta)=100$. Multiple spectra were combined, weighted by exposure time.

Some example spectra are shown in Figs 1, 2 and 3.

Figure 1. INT spectra of Me 2-2: grating R1200B (top) covers wavelengths of $3500-5000 \AA$ and R300V (bottom) covers $3800-7700 \AA$.

Figure 2. INT spectra of Vy 1-2: grating R1200B (top) covers wavelengths of 3500-5000 $\AA$ and R300V (bottom) covers $3800-7700 \AA$. Note the strong recombination lines seen in this object, particularly the $\mathrm{C}_{\text {III }} / \mathrm{O}_{\text {II }}$ blend at $4650 \AA$.

### 2.2 International Ultraviolet Explorer observations

13 nebulae in this sample were observed using the International Ultraviolet Explorer (IUE) satellite. Low-resolution spectra taken with the Short Wavelength Prime (SWP) and Long Wavelength

Prime (LWP) cameras were downloaded from the archive at the Space Telescope Science Institute (STScI), in their final calibrated form. Details of the observations used are given in Table 2. Where several spectra were available, those with the best signal-to-noise

Figure 3. INT spectra of Hu 2-1: grating R1200B (top) covers wavelengths of $3500-5000 \AA$ and R300V (bottom) covers $3800-7700 \AA$.
ratio were selected and combined, weighted by exposure time. For all nebulae, the angular extent of the nebula was smaller than the $I U E$ large aperture ( $10 \times 20 \operatorname{arcsec}^{2}$ ) and so all the nebular flux should have been caught. The measured fluxes were normalized to $\mathrm{H} \beta=100$ using the total $\mathrm{H} \beta$ fluxes listed by Cahn et al. (1992), and dereddened using the extinction coefficients derived from the optical spectra.

### 2.3 Infrared Space Observatory observations

Four nebulae in the sample (Hu 2-1, Me 2-2, NGC 6891 and Vy 22) were observed with the Infrared Space Observatory (ISO) Short Wavelength Spectrometer (SWS), and the fully calibrated spectra were downloaded from the $I S O$ archive. The ISO SWS aperture depends on wavelength, being $14 \times 20 \operatorname{arcsec}^{2}$ for wavelengths of $2.38-12 \mu \mathrm{~m}, 14 \times 27 \operatorname{arcsec}^{2}$ for wavelengths of $12-27.5 \mu \mathrm{~m}, 20 \times$ $27 \mathrm{arcsec}^{2}$ for wavelengths of $27.5-29 \mu \mathrm{~m}$ and $20 \times 33 \mathrm{arcsec}^{2}$ for wavelengths of 29-45 $\mu \mathrm{m}$. These apertures are all larger than the angular dimensions of the nebulae observed, and so the measured fluxes were simply normalized to $F(\mathrm{H} \beta)=100$ using published total $\mathrm{H} \beta$ fluxes from Cahn et al. (1992). The fluxes were then dereddened using the values of $c(\mathrm{H} \beta)$ derived from the optical spectra and the galactic extinction law of Howarth (1983).

### 2.4 Data analysis

The fluxes of lines in the optical and UV spectra were measured using Gaussian line profile fitting techniques within midas. The weak ORLs are often subject to line blending, even at the high resolution of the blue spectra. For example, four lines of the $\mathrm{O}_{\text {II }}$ V10 multiplet are blended with two [S II] lines in the 4068-4076 A wavelength range, and three $\mathrm{C}_{\text {III }} \mathrm{V} 1$ and two $\mathrm{O}_{\text {II }} \mathrm{V} 1$ lines are usually seen to form a single broad feature around $4650 \AA$. In such cases, line fluxes were measured by fitting multiple Gaussians. To obtain a good line fit, it was sometimes necessary to constrain the linewidths to have the same FWHM as a nearby unblended line. In cases where a satisfactory fit was still difficult to obtain, the relative fluxes of recombination lines from the same multiplet were fixed assuming LS coupling; for example, in the case of the $4650 \mathrm{O}_{\text {II }} / \mathrm{C}_{\text {III }}$ feature, the three C III lines at $4647.42,4650.25$ and $4651.47 \AA$ are predicted to have strengths in the ratio $5: 3: 1$. Examples of Gaussian profile fits to blended lines are shown in Fig. 4.

Figure 4. Examples of line deblending in IC 2003 (top) and NGC 7026 (bottom): the $\mathrm{O}_{\text {II }} /\left[\mathrm{S}_{\text {II }}\right]$ blend at 4068-4076 $\AA$ and the $\mathrm{O}_{\text {II }} / \mathrm{C}_{\text {III }}$ blend at 4650 Å.

A full list of the fluxes of all lines measured in the UV, optical and IR spectra for the sample nebulae is given in the Appendices.

## 3 NEBULAR ANALYSIS

### 3.1 Interstellar reddening

Before proceeding with the nebular analysis it was necessary to correct the spectra for the effects of interstellar extinction. The logarithmic extinction at $\mathrm{H} \beta, c(\mathrm{H} \beta)$, was determined by comparing the observed $\mathrm{H} \alpha / \mathrm{H} \beta$ ratio to the value of 2.85 predicted by Storey \& Hummer (1995) for $T_{\mathrm{e}}=10000 \mathrm{~K}$ and $N_{\mathrm{e}}=5000 \mathrm{~cm}^{-3}$, reasonable first guesses for planetary nebulae. All line intensities were then dereddened using the formula
$I(\lambda)=10^{c(H \beta) f(\lambda)} F(\lambda)$,
where $f(\lambda)$ describes an appropriate interstellar extinction curve. We adopt the galactic reddening law of Howarth (1983). The derived values of $c(\mathrm{H} \beta)$ for the sample nebula are given in Table 1. In the case of M 3-27, for which only blue spectra were available, $c(\mathrm{H} \beta)=$ 0.98 was taken from Tylenda et al. (1992).

### 3.2 Physical conditions

For all nebulae in the sample except M 3-27, which is discussed below, temperatures were derived from the [O III]
$\lambda \lambda 4959+5007 / \lambda 4363$ forbidden line ratio. Temperatures were also derived from the ratios [ $\mathrm{N}_{\text {II }}$ ] $\lambda \lambda 6548+6584 / \lambda 5755$, [O ${ }_{\text {II }}$ ] $\lambda \lambda 7320+7330 / \lambda 3727$ and $\left[\mathrm{S}_{\text {II }}\right] \lambda 6731+6717 / \lambda 4068$, for the nebulae where the relevant lines were all detected. The density derived from the [ $\mathrm{O}_{\text {II }}$ ] $\lambda 3727 / 3729$ ratio was adopted for all temperature derivations. Temperatures were also derived in all cases from the ratio of the hydrogen Balmer jump to H11, using the following equation given by Liu et al. (2001)
$T_{\mathrm{e}}=368\left(1+0.259 y^{+}+3.409 y^{++}\right)\left(\frac{\mathrm{BJ}}{\mathrm{H} 11}\right)^{-(3 / 2)}$,
where $y^{+}=\mathrm{He}^{+} / \mathrm{H}^{+}, y^{++}=\mathrm{He}^{++} / \mathrm{H}^{+}$, and $\mathrm{BJ} / \mathrm{H} 11$ is in units of $\AA^{-1}$. Two examples of spectra in the region of the Balmer jump are shown in Fig. 5.

Densities were derived from the forbidden line ratios [Ar Iv] $\lambda 4711 / \lambda 4740,\left[\mathrm{Cl}_{\text {III }}\right] \lambda 5517 / \lambda 5537,\left[\mathrm{~S}_{\text {II }}\right] \lambda 6716 / \lambda 6731$ and [O II] $\lambda 3727 / \lambda 3729$. [О II ] densities were derived for all nebulae in the sample. In the case of other density diagnostics, the lines were not always visible.

The derived electron temperature and density diagnostics are presented in Tables 3 and 4, respectively. Fig. 6 shows the Balmer jump temperature plotted against the [ $\mathrm{O}_{\mathrm{III}}$ ] temperature, and clearly shows that, in almost every case, the Balmer jump temperature is lower than the $\left[\mathrm{O}_{\mathrm{III}}\right]$ temperature. While $T_{\mathrm{e}}([\mathrm{O}$ III $]$ always lies between 7500 and 13000 K , the Balmer jump temperatures cover a larger range of values, from as low as 5000 K to almost 14000 K . Also plotted in Fig. 6 are lines showing the relation between $T_{\mathrm{e}}(\mathrm{BJ})$ and $T_{\mathrm{e}}([\mathrm{O} \mathrm{III}])$ for several values of $t^{2}$, the temperature fluctuation parameter defined by Peimbert (1967).

These results are in line with the results of Liu \& Danziger (1993), who measured $T_{\mathrm{e}}([\mathrm{O} \mathrm{III}])$ and $T_{\mathrm{e}}(\mathrm{BJ})$ for 14 nebulae. They found that a temperature difference corresponding to $t^{2}=0.03$ was typical for their sample. The average value measured for the current sample is higher at $\sim 0.05$.

While the differences observed between $T_{\mathrm{e}}(\mathrm{BJ})$ and $T_{\mathrm{e}}([\mathrm{O}$ III $])$ can theoretically be accounted for by temperature fluctuations within a chemically homogeneous gas (Peimbert 1967), there are some significant difficulties with this interpretation, as outlined in the introduction. In Sections 4.3.3 and 4.4.4, temperatures derived from other recombination line diagnostics are used to shed further light on the temperature structure of the sample nebulae, and evidence against the actual existence of substantial temperature fluctuations is further discussed in Section 6.2.

### 3.2.1 M 3-27

M 3-27 is thought to be an extremely dense, young object (e.g. Kohoutek 1968; Barker 1978). The [O II] $\lambda 3727 / \lambda 3729$ line ratio implies a fairly low density of $3220 \mathrm{~cm}^{-3}$, but the unusually large [O III] $\lambda 4363 / \lambda 4959$ intensity ratio is only possible if the density is very high. To determine the physical conditions in this object, we first made use of the sensitivity of high-order hydrogen Balmer

Figure 6. Balmer jump versus [ $\mathrm{O}_{\mathrm{III}}$ ] temperatures. The lines show the relation between the measured $T_{\mathrm{e}}(\mathrm{BJ})$ and $T_{\mathrm{e}}([\mathrm{O} I I I])$ for different values of the temperature fluctuation parameter $t^{2}$ (see text).
lines to density. Fig. 7 shows the observed intensities of the highorder hydrogen Balmer lines in M 3-27, together with theoretical intensities at varying densities from Storey \& Hummer (1995). The observed intensities are consistent with an electron density of $10^{7} \mathrm{~cm}^{-3}$. Adopting this density, the observed [O III] $\lambda 4959 / \lambda 4363$ ratio yields a temperature of 13000 K .

Subsequent abundance analysis shows that adopting this extremely high density yields a very high $\mathrm{O}^{+} / \mathrm{H}^{+}$abundance, larger than the $\mathrm{O}^{2+} / \mathrm{H}^{+}$abundance. This would imply a nebula of very low excitation, in contradiction with the observations of higher ionization stages such as $\mathrm{Ar}^{3+}$ and the very strong [O III] $\lambda 4363$ emission. Adopting the lower density implied by the [ $\mathrm{O}_{\mathrm{II}}$ ] $\lambda 3727 / \lambda 3729$ ratio to derive the $\mathrm{O}^{+} / \mathrm{H}^{+}$abundance yields a much lower and more plausible value. It seems likely that emission from doubly and more highly ionized species comes predominantly from the very dense core of the nebula, while emission from singly ionized species arises in a lower density outer region. The planetary nebulae Mz 3 (Zhang \& Liu 2002) and M2-24 (Zhang \& Liu 2003) show very similar behaviour, with high ionization species existing predominantly in a dense central core.

Figure 7. High-order hydrogen Balmer line intensities in M 3-27; note that H 14 and H16 are affected by blending.

In subsequent abundance determinations, $T_{\mathrm{e}}=13000 \mathrm{~K}$ is adopted for all species, with $N_{\mathrm{e}}=3220 \mathrm{~cm}^{-3}$ being adopted for singly ionized species and $N_{\mathrm{e}}=10^{7} \mathrm{~cm}^{-3}$ being adopted for all higher ionization stages.

### 3.2.2 Recombination excitation of NII and OII auroral lines

The agreement between the various temperature diagnostics is not always very good. The average $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]\right)$ for the whole sample is 11290 K , while the average $T_{\mathrm{e}}\left(\left[\mathrm{N}_{\text {II }}\right)\right.$ is 13350 K . For the 13 nebulae for which both temperatures are measured, the averages are 10400 and 12110 K , respectively. For $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]\right)$ and $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{II}}\right]\right)$, for the 11 nebulae in which both temperatures are measured, the averages are 10100 and 12800 K . The generally higher temperatures measured for singly ionized species than those for doubly ionized species have sometimes been interpreted as due to the hardening of the radiation field in the less-ionized outer regions of planetary nebulae. However, a more likely explanation is that the lower efficiencies of the [O II] and $\left[\mathrm{N}_{\text {II }}\right]$ cooling lines, compared to those of [ O III], leads to higher electron temperatures in outer nebular regions where singly ionized elements dominate.

Given that generally most of the N and O is in the form of $\mathrm{N}^{2+}$ and $\mathrm{O}^{2+}$, recombination of the doubly ionized ions can contribute significantly to the flux in the [ $\mathrm{N}_{\mathrm{II}}$ ] and [ $\mathrm{O}_{\mathrm{II}}$ ] nebular and auroral lines (Rubin 1986). Liu et al. (2000) calculated radiative and dielectronic recombination coefficients for the metastable levels of [O II], and also used radiative recombination coefficients from Péquignot, Petitjean \& Boisson (1991) and dielectronic recombination coefficients from Nussbaumer \& Storey (1984) for [ $\mathrm{N}_{\text {II }}$ to derive the following formulae for the recombination contributions to the intensities of the [ $\mathrm{N}_{\mathrm{II}}$ ] and [ $\mathrm{O}_{\mathrm{II}}$ auroral lines:

$$
\begin{equation*}
\frac{I_{\mathrm{R}}(\lambda 5754)}{I(\mathrm{H} \beta)}=3.19 t^{0.30} \frac{\mathrm{~N}^{2+}}{\mathrm{H}^{+}}, \tag{3}
\end{equation*}
$$

$\frac{I_{\mathrm{R}}(\lambda 7320+\lambda 7330)}{I(\mathrm{H} \beta)}=9.36 t^{0.44} \frac{\mathrm{O}^{2+}}{\mathrm{H}^{+}}$.
Here, $t=T_{\mathrm{e}} / 10^{4}$. We used these formulae to correct the temperatures derived from the $\left[\mathrm{N}_{\mathrm{II}}\right]$ and $\left[\mathrm{O}_{\mathrm{II}}\right]$ nebular-to-auroral line ratios for the effects of recombination, using $t=T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]\right) / 10^{4}$. The revised temperatures are given in Table 5. We used abundances derived from both CELs and ORLs (see Section 4), and in many cases the recombination contribution is considerable. In Table 5, the three columns listed for each of $T_{\mathrm{e}}\left(\left[\mathrm{N}_{\text {II }}\right]\right)$ and $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{II}}\right]\right)$ are, from left to right, the uncorrected temperature, the temperature corrected for recombination using the CEL ionic abundance, and the temperature corrected using the ORL ionic abundance. In three cases, if the abundances derived from ORLs are used, recombination can account for the entire flux of the auroral lines (DdDm 1 and $\mathrm{Sp} 4-1$ for the [ $\mathrm{N}_{\mathrm{II}}$ ] lines and $\mathrm{Vy} 2-2$ for the [ $\mathrm{O}_{\mathrm{II}}$ ] lines), in which case the line ratios are no longer a useful temperature diagnostic. Accounting for recombination excitation brings the temperatures into somewhat better agreement in many cases.

Recombination excitation may also enhance the [ $\mathrm{S}_{\text {II }}$ ] $\lambda 4068$ and $\lambda 4076$ lines, which are also blended with lines from the O II V10 multiplet. However, adequate accounting for the effects of recombination on these lines is hampered by the lack of effective recombination coefficients for the $\left[\mathrm{S}_{\text {II }}\right]$ metastable levels. Given the blending of these lines and the possible effects of recombination excitation, the [ $\mathrm{S}_{\text {II }}$ temperatures may be subject to considerable errors.

### 3.3 Temperatures from helium emission-line ratios

Table 3 shows that in almost every case, the electron temperature derived from the hydrogen Balmer jump is lower than that derived from the [ $\mathrm{O}_{\mathrm{III}}$ ] forbidden lines. This phenomenon was first observed

Table 5. Corrected electron temperatures (in K ), accounting for recombination excitation of the nebular and auroral lines.

by Peimbert (1971), and interpreted by him and many subsequent investigators as evidence for substantial temperature fluctuations in the nebulae. The emissivity of the hydrogen continuum has a negative power-law dependence on $T_{\mathrm{e}}$, while the emissivities of the [ $\mathrm{O}_{\text {II }}$ ] lines increase exponentially with temperature. Thus, in the presence of temperature fluctuations, the CEL emission will be strongly weighted towards the hottest regions of the nebula, while the hydrogen continuum emission will be weighted towards the cooler regions.

A problem with the temperature fluctuation scenario is that in many cases the magnitude of the fluctuations required to reconcile $T_{\mathrm{e}}([\mathrm{O} I I])$ and $T_{\mathrm{e}}(\mathrm{BJ})$ is larger than anything predicted by photoionization modelling. Alternative explanations for the observed temperature discrepancies have included the presence of strong density inhomogeneities (Viegas \& Clegg 1994), extra heating from shock waves (Peimbert, Sarmiento \& Fierro 1991) and abundance discontinuities (Torres-Peimbert, Peimbert \& Peña 1990). Direct observational evidence for these mechanisms is lacking, however. Liu et al. (2000) proposed that the presence of cold hydrogen-deficient knots within the main body of the nebula could resolve the temperature discrepancies. In this case, CEL emission would come almost entirely from the hot, normal component of the nebula, with most of the ORL emission originating from the cold knots. Helium lines would be emitted from both regions. Liu (2003) showed that if H-deficient knots were present, one would expect to find that
$T_{\mathrm{e}}\left(\mathrm{O}_{\text {II }}\right) \lesssim T_{\mathrm{e}}\left(\mathrm{He}_{\mathrm{I}}\right) \lesssim T_{\mathrm{e}}(\mathrm{BJ}) \lesssim T_{\mathrm{e}}\left(\left[\mathrm{O}_{\text {III }}\right]\right)$,
where $T_{\mathrm{e}}\left(\mathrm{He}_{\mathrm{I}}\right)$ is the temperature derived from the helium line ratios $\lambda 5876 / \lambda 4471$ and $\lambda 6678 / \lambda 4471$, which have a weak dependence on temperature, and $T_{\mathrm{e}}\left(\mathrm{O}_{\text {II }}\right)$ is the temperature derived from temperature-sensitive $\mathrm{O}_{\text {II }}$ recombination line ratios. In this section we present measurements of $T_{\mathrm{e}}\left(\mathrm{He}_{\mathrm{I}}\right)$ for the sample nebulae. The helium line emissivities were taken from Smits (1996), and the effects of collisional excitation from the metastable $2 \mathrm{~s}^{3} \mathrm{~S}$ level were corrected for using the formulae given by Kingdon \& Ferland (1995). The temperatures we derive are given in Table 6. In almost every case they are lower than the temperatures derived from forbid-

den line diagnostics, and also lower than the hydrogen Balmer jump temperature. The temperatures derived from the $\lambda 5876 / \lambda 4471$ ratio range from 1000 to 7960 K .
The value of $T_{\mathrm{e}}(\mathrm{He}$ I) given by the $\lambda 5876 / \lambda 4471$ line ratio is likely to be more reliable than the value derived from the $\lambda 6678 / \lambda 4471$ line ratio, because the $\lambda 5876$ line is roughly three times stronger, and the smaller wavelength difference means that the former ratio is less susceptible to flux calibration and reddening errors. Therefore, in subsequent analysis the temperature derived from $\lambda 5876 / \lambda 4471$ is adopted as $T_{\mathrm{e}}(\mathrm{He} \mathrm{I})$.

### 3.4 Temperatures derived from $\mathrm{O}_{\text {II }}$ recombination lines

In general, the ratios of heavy element recombination lines depend very little on electron temperature. However, by comparing lines from different multiplets in which there is a difference in angular momentum, the temperature sensitivity is maximized. If the nebulae contain very cold ionized regions, the temperature measured from heavy element recombination lines should be close to the true temperature of the cold regions.

In this section we present measurements of the temperatures of the sample nebulae based on several $\mathrm{O}_{\text {II }}$ line ratios. The ratios of the strongest $3 \mathrm{~s}-3$ p and 3 p- 3 d lines, $\lambda 4649$ and $\lambda 4075$ to the strong $3 \mathrm{~d}-4 \mathrm{f}$ line $\lambda 4089$ are likely to provide the most reliable temperatures as these three lines can only be produced by recombination from the $2 \mathrm{p}^{23} \mathrm{P}_{2}$ level of $\mathrm{O}^{2+}$. The line ratios $\lambda 4414 / \lambda 4089$ and $\lambda 4072 / \lambda 4089$ are also used to derive temperatures, but in this case the lines form by recombination from different levels. Liu (2003) noted that for several nebulae, the latter line ratios implied temperatures considerably higher than the other $\mathrm{O}_{\text {II }}$ diagnostics, and suggested that a possible explanation could be that the $2 \mathrm{p}^{2}{ }^{3} \mathrm{P}_{2}$ level was underpopulated relative to its statistical equilibrium value, thus compromising the reliability of these line ratios as temperature diagnostics.
In Table 7 we give the temperature values derived from the line ratios $\lambda 4075 / \lambda 4089, \lambda 4649 / \lambda 4089, \lambda 4414 / \lambda 4089, \lambda 4072 / \lambda 4089$ and also for the ratio of the sum of the five strongest lines of the V1

multiplet to the $\lambda 4089$ line. The adopted $\mathrm{O}_{\text {II }}$ temperature given is the average of those derived from the $\lambda 4075 / \lambda 4089$ and V1/ $\lambda 4089$ ratios. The V1/ $\lambda 4089$ ratio is preferred to $\lambda 4649 / \lambda 4089$, because the $\lambda 4649$ line is blended with $\mathrm{C}_{\text {III }}$ lines of comparable strength and thus its flux can be uncertain. In addition, Tsamis et al. (2003) and Ruiz et al. (2003) have shown that the relative intensities of O iI V1 multiplet components are dependent on nebular density, in the sense that they deviate from local thermodynamic equilibrium (LTE) predictions for those nebulae having electron densities lower than the critical densities of the sublevels of the $\mathrm{O}^{2+}{ }^{3} \mathrm{P}$ groundstate parent. Using all the lines from the V1 multiplet reduces the effects of any errors caused by line blending as well as the effects of deviations from LTE multiplet line ratios at low nebular densities.

It can be seen from Table 7 that, in many cases, very low temperatures are implied by $\mathrm{O}_{\text {II }}$ line ratios, often $<10^{3} \mathrm{~K}$. Such temperatures provide strong evidence for the existence of a very cold ionized component in planetary nebulae. The temperatures derived from the [ $\mathrm{O}_{\mathrm{III}}$ ] forbidden lines, the hydrogen Balmer jump, He ilines and $\mathrm{O}_{\text {II }}$ recombination lines follow in almost every case the relation expected in the presence of cold, ionized, hydrogen-deficient material. The final adopted temperatures from these four diagnostics are given in Table 8.

## 4 ABUNDANCE ANALYSIS

In this section we present the abundances derived for the 23 sample nebulae, from both CELs and ORLs.

### 4.1 Ionic abundances from CELs

Abundances are derived for the sample nebulae from lines of C, $\mathrm{N}, \mathrm{O}, \mathrm{Ne}, \mathrm{S}, \mathrm{Ar}, \mathrm{Cl}$ and Fe . To derive the abundances we adopt in all cases the [ $\mathrm{O}_{\mathrm{III}}$ ] temperature, in light of the uncertainties introduced into temperature determinations from singly ionized species by recombination excitation of the relevant lines.

The densities adopted were the average of the values implied by the diagnostics available, as listed in the final column of Table 4. IR lines often have critical densities comparable with typical nebular densities, and so any density variations present may significantly affect abundances derived from IR lines. For the nebulae analysed here, however, all the IR lines observed (listed in Appendix B) have critical densities much higher than the densities measured from the optical CEL diagnostics, and therefore the same electron density was adopted for both IR and optical abundance determinations from CELs.

The EQUIB code was used to solve the statistical equilibrium equations for multilevel atomic models, giving level populations and line emissivities for the appropriate physical conditions. The derived abundances are presented in Tables 9 (carbon), 10 (nitrogen), 11 (oxygen), 12 (neon), 13 (sulphur) and 14 (chlorine, argon and iron). The atomic data references used for the statistical calculations are listed in Appendix B.

### 4.2 Ionic abundances from ORLs

### 4.2.1 Helium abundances

Helium to hydrogen abundance ratios were derived using the hydrogen Balmer jump temperatures listed in Table 8 for all of the recombining ions, $\mathrm{H}^{+}, \mathrm{He}^{+}$and $\mathrm{He}^{2+}$ (we note that the adoption instead for $\mathrm{He}^{+}$of the He I temperatures listed in Table 8 would lead to lower derived $\mathrm{He}^{+}$abundances). Effective recombination coefficients were taken from Brocklehurst (1972). Case A was assumed for the $\lambda 4471$ and $\lambda 5876$ triplets, and case $B$ for the $\lambda 6678$ singlet. Collisional effects were taken into account using the formulae derived by Kingdon \& Ferland (1995). The results are presented in Table 15.

In most cases, the abundances derived from the three lines agree to within a few per cent. However, for two nebulae (DdDm 1 and

${ }^{a} 5007$ flux not available; 4363 and 4959 lines used to derive abundance.

NGC 6807) the abundance derived from the $\lambda 6678$ line is much lower than that derived from the other lines. The problem cannot be accounted for by reddening errors - in both cases the intensity of the line is very low compared to $\lambda 4471$ even before the correction for interstellar extinction. Another possible explanation is that there is a

departure from pure case B recombination. Such a departure may be caused by the destruction of He I Lyman photons by dust grains or photoionization of neutral hydrogen. This mechanism is certainly plausible in the case of NGC 6807, for which high densities are implied by the standard diagnostics ( $34000 \mathrm{~cm}^{-3}$ from the [Ar Iv] $\lambda 4740 / 4711$ ratio). Finally, underlying absorption may reduce the measured fluxes. Clegg, Peimbert \& Torres-Peimbert (1987) find

evidence for underlying absorption of $\mathrm{He}_{\mathrm{I}}$ lines in their study of DdDm 1.

The extremely low $\mathrm{He} / \mathrm{H}$ abundance derived in the case of $\mathrm{Cn} 3-1$ must be due to a considerable amount of neutral helium being present in this object. It is known to be an extremely low-excitation object (e.g. French 1981; Aller \& Czyzak 1983), and this is evident in the
current observations. The [O III] nebular lines are usually among the strongest in optical nebular spectra, with $I(\lambda 4959+5007) \gg I(\mathrm{H} \beta)$, but in this case $I(\lambda 4959+5007) \sim 0.25 I(\mathrm{H} \beta)$. Zhang \& Liu (2003) suggest using
$\frac{\mathrm{He}}{\mathrm{H}}=\frac{\mathrm{S}^{+}+\mathrm{S}^{2+}}{\mathrm{S}^{2+}} \frac{\mathrm{He}^{+}}{\mathrm{H}^{+}}$,
to correct for the unobserved neutral helium; this yields a total $\mathrm{He} / \mathrm{H}$ abundance of 0.063 , which is still very low and is certainly still an underestimate. Alternatively, Peimbert \& Costero (1969) suggest the following ionization correction factor (ICF):
$\frac{\mathrm{He}}{\mathrm{H}}=\left[\left(0.87 \times \frac{\mathrm{S}}{\mathrm{S}-\mathrm{S}^{+}}\right)+\left(0.13 \times \frac{\mathrm{O}}{\mathrm{O}-\mathrm{O}^{+}}\right)\right]\left(\frac{\mathrm{He}^{+}}{\mathrm{H}^{+}}\right)$.
This formula yields the very high value of $\mathrm{He} / \mathrm{H}=0.173$. An accurate determination of the total chemical abundances in $\mathrm{Cn} 3-$ 1 would need detailed photoionization modelling, and the lack of knowledge of the helium ionization structure makes applying an empirical ICF very uncertain for this object. Therefore, only ionic abundances are given for $\mathrm{Cn} 3-1$.

### 4.2.2 $\mathrm{C}^{2+} / \mathrm{H}^{+}, \mathrm{C}^{3+} / H^{+}$and $\mathrm{C}^{4+} / H^{+}$

Recombination line $\mathrm{C}^{2} / \mathrm{H}^{+}$abundances for the sample nebula were derived using the strong $\lambda 4267$ line, recorded at high signal-to-noise in all spectra except that of the known carbon-poor (Clegg et al. 1987) halo planetary nebula DdDm 1. Abundances derived for this line have long been known to be high compared to those derived from the UV C III] $\lambda 1906,1908$ lines, and this had led to its pure recombination origin being questioned (e.g. Barker 1982).

In high signal-to-noise spectra, it is possible to detect recombination lines from states higher than the $4 f^{2} F^{o}$ level, such as the $4 f^{2} F^{o}$ $-n g^{2} G$ series which feeds the $\lambda 4267$ line. The relative intensities of these lines can be compared to the predictions of recombination theory to determine whether the $\lambda 4267$ line can be safely attributed to recombination alone or whether some other process might be overpopulating the $4 f^{2} \mathrm{~F}^{0}$ level and leading to overestimated $\mathrm{C}^{2+} / \mathrm{H}^{+}$ abundances. Wesson et al. (2003) and Wesson \& Liu (2004) have shown that for both Abell 30 and NGC 6543 the strengths of lines from high in the recombination ladder were in very good agreement with theoretical predictions. Unfortunately for the nebulae under consideration here, high-excitation lines are not seen in the majority of cases. A clear detection is found in only one case, M 1-73, where the $\lambda 64624 \mathrm{f}-6 \mathrm{~g}$ line is seen. Relative to $\lambda 4267=1.000$, the observed line strength is 0.112 , which is in agreement within the errors with the predicted value of 0.103 .

Although high excitation lines are not generally seen in our spectra, in the light of the very good agreement with theory found in this work for these lines in the cases of Abell 30 and NGC 6543, and for other nebulae such as M2-36 (Liu et al. 2001) and NGC 6153 (Liu et al. 2000), it seems very safe to attribute the $\lambda 4267$ line flux to recombination alone. Given its good detection in all spectra and insensitivity to the assumption of case A or case B recombination, $\mathrm{C}^{2+} / \mathrm{H}^{+}$abundances for the sample nebulae were derived from $\lambda 4267$ only. The abundances determined are listed in Table 16.

C III lines are detected in all spectra except that of DdDm 1, where the blend of three C III and two O II lines in the 4650-Å region is detected but not well enough to be adequately fitted. This nebula is a known halo Type iv object, with much lower heavy element abundances than for typical galactic disc objects (e.g. Clegg et al. 1987; Torres-Peimbert et al. 1997). In the case of Sp 4-1, the $\lambda 4650$ feature is swamped by a broad stellar emission line; the angular diameter

of the nebula was too small for a nebular spectrum excluding the central star to be extracted. However, the $\lambda 4187$ line is detected and so a $\mathrm{C}^{3+} / \mathrm{H}^{+}$abundance can be derived for the nebula.

The agreement between abundances derived from the V1 multiplet and from the V18 $\lambda 4187$ line is reasonable, and where both are available, the adopted $\mathrm{C}^{3+} / \mathrm{H}^{+}$abundance is the mean of the two values. The results are presented in Table 17.

The C iv line at $4658.64 \AA$ As blended in many cases with [Fe III] at $4658.10 \AA$. Where no $\mathrm{He}^{2+}$ emission is seen, all the line flux is attributed to [ Fe III]. If $\mathrm{He}^{2+}$ is seen and other [ Fe III] lines are present, the contribution of [ $\left.\mathrm{Fe}_{\mathrm{III}}\right]$ to the line flux can be calculated using the abundance derived from the other [ Fe III] lines. If no other [ Fe III] lines are seen and $\mathrm{He}^{2+}$ is present, the line flux is attributed to Civ. Abundances derived from this line are presented in Table 18.

### 4.2.3 $\mathrm{N}^{3+} / \mathrm{H}^{+}$and $\mathrm{N}^{2+} / \mathrm{H}^{+}$

N III lines were detected from all nebulae in the sample, but effective recombination coefficients are available for only two lines, $\lambda 4379$ and $\lambda 4640$ (Péquignot et al. 1991). Abundances derived from the $\lambda 4640$ line are invariably higher than those derived from $\lambda 4379$, by factors ranging from 1.2 to 15 . The former line can be strongly affected by continuum fluorescence (Ferland 1992), and so is not used in these abundance determinations. The $\lambda 4379$ line is detected from 11 nebulae, and the abundances derived from it for these nebulae are shown in Table 19. Nit lines were detected from 16 of the 23 sample nebulae, and abundances derived from them are given in Table 20.

### 4.2.4 $\mathrm{O}^{2+} / \mathrm{H}^{+}$

Oif recombination lines are seen in all the nebulae in the sample, with several nebulae exhibiting particularly rich spectra with many lines visible. Abundances derived from them are presented in Table 21. As well as abundances derived from each individual line, the co-added intensities of lines within each multiplet seen are used to derive an abundance for the multiplet, and abundances for the 3d-4f transitions are derived from the co-added intensities of the $3 \mathrm{~d}-4 \mathrm{f}$ lines visible in the spectra. The abundance derived from

the V5 multiplet is invariably higher than the average derived from other multiplets; an unknown blend could be enhancing the strengths of the two lines at $\lambda 4415,4417$, or there could be errors in the available recombination coefficients for this multiplet. In light of the probable unreliability of V5 abundances, the abundance adopted is the mean of the values for all 3-3 multiplets excluding V5, and the $3 \mathrm{~d}-4 \mathrm{f}$ value.

### 4.2.5 $\mathrm{Ne}^{2+} / \mathrm{H}^{+}$

Neon ORLs are seen in the spectra of eight of the 23 sample nebulae. In most cases the only transitions seen are 3d-4f transitions, and recombination coefficients assuming intermediate coupling calculated by Storey (unpublished) are used to derive abundances from them. These coefficients assume that the three fine structure levels of the $2 \mathrm{p}^{4}{ }^{3} \mathrm{P}_{2,1,0}$ ground terms of $\mathrm{Ne}^{2+}$ are thermalized. However, the critical densities of the ${ }^{3} \mathrm{P}_{1}$ and ${ }^{3} \mathrm{P}_{0}$ levels are quite high ( $>10^{4} \mathrm{~cm}^{-3}$ ), and so at lower densities their level populations may depart from the thermal equilibrium values. The equilibrium level populations for the ${ }^{3} \mathrm{P}_{2,1,0}$ levels are in the ratio $1: 0.6: 0.2$, but in the low-density limit the ${ }^{3} \mathrm{P}_{1,0}$ levels are completely unpopulated. The strongest $3 \mathrm{~d}-4 \mathrm{f}$ transitions arise from the ${ }^{3} \mathrm{P}_{2}$ level, and so at low

${ }^{a}$ V28 abundance excluded from average due to being based only on one weak line in a noisy region. ${ }^{b}$ V19 abundance excluded from average as $\lambda 4156$ line may be affected by blending. ${ }^{c} \lambda 4156$ line excluded from multiplet abundance determination due to possible blending; with the line included the abundance is $1.614 \times 10^{-3}$. ${ }^{d}$ Excluded from multiplet abundance due to blending with $\mathrm{He}_{\mathrm{I}} \lambda 4120.86$. ${ }^{e}$ Line excluded from multiplet abundance determination due to possible blending.
$3 \mathrm{~d}-4 \mathrm{f}$ abundances are available, the $\mathrm{Ne}^{2+} / \mathrm{H}^{+}$abundance should be considered an upper limit.
$\mathrm{Ne}^{2+} / \mathrm{H}^{+}$abundances derived for the sample nebulae are given in Table 22.

## 5 TOTAL ELEMENTAL ABUNDANCES FROM CELS AND ORLS

From the ionic abundances derived in the previous section, total elemental abundances are derived, correcting for unseen ionization stages using the ionization correction factor scheme of Kingsburgh \& Barlow (1994).

### 5.1 C/H

Total carbon abundances are derived in several ways. CEL abundances are derived for the nebulae for which UV spectra are available. If no $\mathrm{C}^{4+}$ is present, then $\mathrm{C} / \mathrm{H}$ is given simply by the sum of $\mathrm{C}^{+}, \mathrm{C}^{2+}$ and $\mathrm{C}^{3+}$ if all are seen. If $\mathrm{C}^{+}$is not seen, equation (8) is used; if only $\mathrm{C}^{2+}$ is seen, then equation (9) is used:

$$
\begin{align*}
& \frac{\mathrm{C}}{\mathrm{H}}=\frac{\mathrm{O}^{+}+\mathrm{O}^{2+}}{\mathrm{O}^{2+}} \frac{\mathrm{C}^{2+}+\mathrm{C}^{3+}}{\mathrm{H}^{+}}  \tag{8}\\
& \frac{\mathrm{C}}{\mathrm{H}}=\frac{\mathrm{O}}{\mathrm{O}^{2+}} \frac{\mathrm{C}^{2+}}{\mathrm{H}^{+}} \tag{9}
\end{align*}
$$

Table 22. $\mathrm{Ne}^{2+} / \mathrm{H}^{+}$recombination line abundances in the sample nebulae.

|  |  |  |  |  |

No $\mathrm{C}^{+} / \mathrm{H}^{+}$abundance is available from ORLs. To derive total ORL abundances, the unseen $\mathrm{C}^{+}$is corrected for using $\operatorname{icf}(\mathrm{C})=$ $1+\mathrm{O}^{+} / \mathrm{O}^{2+}$, with $\mathrm{C} / \mathrm{H}$ then given by

$$
\begin{equation*}
\frac{\mathrm{C}}{\mathrm{H}}=i c f(\mathrm{C}) \frac{\left(\mathrm{C}^{2+}+\mathrm{C}^{3+}+\mathrm{C}^{4+}\right)}{\mathrm{H}^{+}} . \tag{10}
\end{equation*}
$$

In the case of DdDm 1 , where only $\mathrm{C}^{+}$and $\mathrm{C}^{2+}$ abundances are available, no ionization correction is applied, in light of the relatively low degree of ionization implied by the oxygen ionic ratios and lack of $\mathrm{He}^{2+}$ in the nebula. For nebulae where $\mathrm{He}^{2+} / \mathrm{He}$ is small, the $\lambda 4658$ line, if detected, is attributed to [ Fe III], as discussed in Section 4.2, and the total carbon abundance is derived from the above formula simply neglecting $\mathrm{C}^{4+} / \mathrm{H}^{+}$. Where UV spectra are available, an alternative means of correcting for the unseen $\mathrm{C}^{+}$is to assume that the $\mathrm{C}^{+} / \mathrm{C}^{2+}$ ratio derived from CELs is also applicable to ORLs. However, Tsamis (2002) and Tsamis et al. (2004) find that, in general, carbon ionic ratios derived from CELs are not equal to those derived from ORLs. Therefore the ionization correction scheme is preferred.

Total carbon abundances from CELs are given in Table 23, and those from ORLs are given in Table 24.

### 5.2 N/H

Total nitrogen abundances are somewhat uncertain in the cases where only optical spectra are available. The only ionization stage which is then observed is $\mathrm{N}^{+}$, which generally accounts for only a small fraction ( $\leqslant 10$ per cent) of the total nitrogen abundance. The unobserved ionization stages are corrected for by assuming that $\mathrm{N} / \mathrm{N}^{+}=\mathrm{O} / \mathrm{O}^{+}$, so that $\mathrm{N} / \mathrm{H}=\left(\mathrm{O} / \mathrm{O}^{+}\right)\left(\mathrm{N}^{+} / \mathrm{H}^{+}\right)$.

Where UV spectra are available, the $\mathrm{N} / \mathrm{H}$ abundance is more securely derived. The $\lambda 1750 \mathrm{NIII}]$ line is used to derive $\mathrm{N}^{2+} / \mathrm{H}^{+}$

not available, we use the relation $\mathrm{N}^{+} / \mathrm{N}=\mathrm{O}^{+} / \mathrm{O}$ to correct for the $\mathrm{N}^{+}$ present. Where only $\mathrm{N}^{2+} / \mathrm{H}^{+}$abundances are available from ORLs, the ionization correction scheme of Kingsburgh \& Barlow (1994) does not give a correction for the unseen ionization stages. In this case, $\mathrm{N} / \mathrm{H}$ is estimating assuming $\mathrm{N} / \mathrm{N}^{2+}=\mathrm{O} / \mathrm{O}^{2+}$, based on the similarities of their ionization potentials. This relation is also used to derive the total N/H abundance from CELs for M 3-27, where only $\mathrm{N}^{2+} / \mathrm{H}^{+}$is available, from UV observations.

Total N/H abundances from CELs and ORLs are presented in Table 25.

### 5.3 O/H

For CELs, given the possible strong effect of recombination on abundances derived from the $\lambda \lambda 7320,7330$ lines, $\mathrm{O}^{+} / \mathrm{H}^{+}$abundances are derived from $\lambda \lambda 3726,3729$ only. Recombination can also be significant for these lines, and abundances derived from them may be considered upper limits. Given that $\mathrm{O}^{+} / \mathrm{O}^{2+}$ is generally not large, the overall errors introduced into the $\mathrm{O} / \mathrm{H}$ abundance by this possible uncertainty are small. The ionization correction factor for O is given by $\left[\left(\mathrm{He}^{+}+\mathrm{He}^{2+}\right) / \mathrm{He}^{+}\right]^{2 / 3}$, following which $\mathrm{O} / \mathrm{H}=\mathrm{ICF}(\mathrm{O})$ $\left(\mathrm{O}^{+} / \mathrm{H}^{+}+\mathrm{O}^{2+} / \mathrm{H}^{+}\right)$.

Only $\mathrm{O}^{2+} / \mathrm{H}^{+}$abundances are available from ORLs, and to derive total oxygen abundances for ORLs, we assume that the value of $\mathrm{O}^{+} / \mathrm{O}^{2+}$ derived from CELs is also applicable to ORLs. Total oxygen abundances are given in Table 26.

### 5.4 Ne/H

Total neon abundances are based on the derived values of $\mathrm{Ne}^{2+} / \mathrm{H}^{+}$ only. [ $\mathrm{Ne}_{\mathrm{IV}}$ ] lines are seen in the optical and/or UV in five cases, but the ionization correction scheme of Kingsburgh \& Barlow (1994) does not provide an ICF equation for cases where $\mathrm{Ne}^{2+}$ and $\mathrm{Ne}^{3+}$
are the only ionization stages seen, and so instead total $\mathrm{Ne} / \mathrm{H}$ abundances are derived using
$\frac{\mathrm{Ne}}{\mathrm{H}}=\frac{\mathrm{O}}{\mathrm{O}^{2+}} \frac{\mathrm{Ne}^{2+}}{\mathrm{H}^{+}}$.
The total $\mathrm{Ne} / \mathrm{H}$ abundances thus derived are given in Table 27.

### 5.5 S/H, Cl/H and Ar/H

Sulphur, chlorine and argon abundances are available from CELs only. For sulphur, in most cases both $\mathrm{S}^{+}$and $\mathrm{S}^{2+}$ are seen. If both the $\lambda 6717,6731$ and $\lambda 4068,4076$ lines are seen, the $\mathrm{S}^{+} / \mathrm{H}^{+}$abundance is taken from the $\lambda 6717,6731$ lines only, as the $\lambda 4068,4076$ lines are blended with $\mathrm{O}_{\text {II }}$ lines of similar strength, and are probably also enhanced by recombination excitation. For M 3-27, M 3-34, NGC 6833 and $6879, \mathrm{~S}^{+} / \mathrm{H}^{+}$is only available from $\lambda 4068,4076$, and so the derived $\mathrm{S} / \mathrm{H}$ may be overestimated.

Where both $\mathrm{S}^{+}$and $\mathrm{S}^{2+}$ are seen, $\mathrm{S} / \mathrm{H}$ is derived using
$\frac{\mathrm{S}}{\mathrm{H}}=\left[1-\left(1-\frac{\mathrm{O}^{+}}{\mathrm{O}}\right)^{3}\right]^{-1 / 3}\left(\frac{\mathrm{~S}^{+}}{\mathrm{H}^{+}}+\frac{\mathrm{S}^{2+}}{\mathrm{H}^{+}}\right)$.
For M 1-73, M 3-27 and M 3-34, $\mathrm{S}^{2+}$ is not seen, and the following equation from Kingsburgh \& Barlow (1994) is used to calculate its abundance from the observed $\mathrm{S}^{+} / \mathrm{H}^{+}$abundance:

$$
\begin{equation*}
\frac{\mathrm{S}^{2+}}{\mathrm{S}^{+}}=4.677+\left(\frac{\mathrm{O}^{2+}}{\mathrm{O}^{+}}\right)^{0.433} \tag{13}
\end{equation*}
$$

Argon abundances are derived using the following equation in all except four cases:
$\frac{\mathrm{Ar}}{\mathrm{H}}=\left[\frac{1}{1-\left(\mathrm{N}^{+} / \mathrm{N}\right)}\right]\left(\frac{\mathrm{Ar}^{2+}}{\mathrm{H}^{+}}+\frac{\mathrm{Ar}^{3+}}{\mathrm{H}^{+}}+\frac{\mathrm{Ar}^{4+}}{\mathrm{H}^{+}}\right)$.

The exceptions are $\mathrm{Hu} 1-1$ and $\mathrm{M} 3-27$, for which only $\mathrm{Ar}^{3+}$ is seen and the following equation is used
$\frac{\mathrm{Ar}}{\mathrm{H}}=\frac{\mathrm{Ne}}{\mathrm{Ne}^{2+}} \frac{\mathrm{Ar}^{3+}}{\mathrm{H}^{+}}$,
and $\mathrm{Cn} 3-1$ and $\mathrm{M} 1-73$, in which only $\mathrm{Ar}^{2+}$ is seen, in which case the following equation applies:

$$
\begin{equation*}
\frac{\mathrm{Ar}}{\mathrm{H}}=1.87\left(\frac{\mathrm{Ar}^{2+}}{\mathrm{H}^{+}}\right) \tag{16}
\end{equation*}
$$

Kingsburgh \& Barlow (1994) do not give an ICF for chlorine. Liu et al. (2000) give the following equation based on the similarities between the ionization potentials of Cl and S ion stages:

$$
\begin{equation*}
\frac{\mathrm{Cl}}{\mathrm{H}}=\frac{\mathrm{S}}{\mathrm{~S}^{2+}} \frac{\mathrm{Cl}^{2+}}{\mathrm{H}^{+}} . \tag{17}
\end{equation*}
$$

Total $\mathrm{Ar}, \mathrm{S}$ and Cl abundances derived from the above equations are given in Tables 28, 29 and 30, respectively.

### 5.6 Total CEL and ORL abundances

Total abundances for the sample nebulae and averages for the sample are given in Table 31, together with the average CEL values derived for a southern sample by Kingsburgh \& Barlow (1994), and solar abundances from Allende Prieto, Lambert \& Asplund (2002), Allende Prieto \& Lambert (2001) and Grevesse \& Sauval (1998). Abundances are given on a logarithmic scale where $\mathrm{N}(\mathrm{H})=12$. The Type IV metal-deficient halo planetary nebula DdDm 1 is excluded from the average sample abundances. The average abundances derived for the current sample are slightly lower than those found by Kingsburgh \& Barlow (1994). This is probably due to the radial metallicity gradient of the Milky Way: the sample of Kingsburgh \& Barlow was of southern planetary nebulae and consisted mainly of nebulae inside the solar circle. The nebulae analysed here are all Northern hemisphere objects which are predominantly at larger galactocentric distances.

### 5.7 Comparison with previous results

Table 32 shows the results derived in this section alongside total elemental abundances determined previously. Only CEL abundances are compared; almost invariably only CEL abundances were derived in previous works, with the occasional exception of carbon abundances from the C II $\lambda 4267$ line. Generally good agreement is seen between the results obtained in this work and previous determinations, with typical differences being 0.2 dex or less. Larger differences may be seen for $\mathrm{S}, \mathrm{Ar}$ and Cl ; discrepancies with previous studies for these elements are likely to arise because the lines used to derive these abundances are quite weak, and the ICFs used to derive total abundances are occasionally quite large, giving rise to further potential uncertainty.

Table 31. Total elemental abundances for all nebulae in the sample, on a logarithmic scale where $\mathrm{N}(\mathrm{H})=12$.

| Nebula | He | C |  | N |  | O |  | Ne |  | $\begin{gathered} \mathrm{S} \\ \mathrm{CEL} \end{gathered}$ | $\begin{gathered} \mathrm{Cl} \\ \mathrm{CEL} \end{gathered}$ | $\begin{gathered} \mathrm{Ar} \\ \mathrm{CEL} \end{gathered}$ |

## 6 DISCUSSION

### 6.1 Abundance discrepancy factors

Abundance discrepancy factors for all ions where ORL and CEL abundances have been derived are shown in Table 33. In every case, the ionic abundances derived from ORLs are higher than those derived from CELs. It is evident that while the typical discrepancy factor is $2-3$, some objects in this sample show much larger discrepancies. The ratio of the ORL to CEL $\mathrm{O}^{2+} / \mathrm{H}^{+}$abundance is the best determined adf, as it is derived from the optical spectra alone without the extra potential systematic errors involved in normalizing UV data to the same scale as the optical. IC 2003 and Vy 1-2 show moderately large discrepancies, with $\operatorname{adf}\left(\mathrm{O}^{2+}\right)=7.3$ and 6.2 , respectively, while DdDm 1 and Vy 2-2 show very large discrepancies, both with $\operatorname{adf}\left(\mathrm{O}^{2+}\right)=11.8$.

The abundance discrepancies for ions of different elements are generally broadly similar, a pattern seen before for nebulae analysed by Liu et al. $(1995,2000,2001)$ and Tsamis et al. (2004), and in the analysis of NGC 6543 by Wesson \& Liu (2004). However, some systematic differences are seen. It is notable that adf $\left(\mathrm{Ne}^{2+}\right)$ is always larger than $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$, by factors of around 2. As discussed in Section 4.2.5, the assumption of thermal equilibrium for the $2 \mathrm{p}^{4}{ }^{3} \mathrm{P}_{2,1,0}$ fine structure levels of the ground term of $\mathrm{Ne}^{2+}$ may be unrealistic, resulting in overestimated abundance from 3d-4f transitions by factors of up to 1.8. As most of the $\mathrm{Ne}_{\text {II }}$ lines observed in the sample nebulae are $3 \mathrm{~d}-4 \mathrm{f}$ lines, it is likely that departures from thermal equilibrium are behind this discrepancy.

In the following sections, possible explanations for the observed ORL/CEL abundance discrepancies are considered.

### 6.2 Evidence for cold, $\mathbf{H}$-deficient inclusions

The earliest interpretation of observed nebular temperature discrepancies was in terms of temperature fluctuations within the nebulae (Peimbert 1967, 1971). The mean temperature $T_{0}$ and the temperature fluctuation parameter $t^{2}$ were defined by Peimbert (1967) as
$T_{0}\left(\mathrm{X}^{\mathrm{i}+}\right)=\frac{\int T_{\mathrm{e}} N_{\mathrm{e}} N\left(\mathrm{X}^{\mathrm{i}+}\right) \mathrm{d} V}{\int N_{\mathrm{e}} N\left(\mathrm{X}^{\mathrm{i}+}\right) \mathrm{d} V}$,
$t^{2}\left(\mathrm{X}^{\mathrm{i}+}\right)=\frac{\int\left(T_{\mathrm{e}}-T_{0}\right)^{2} N_{\mathrm{e}} N\left(\mathrm{X}^{\mathrm{i}+}\right) \mathrm{d} V}{T_{0}^{2} \int N_{\mathrm{e}} N\left(\mathrm{X}^{\mathrm{i}+}\right) \mathrm{d} V}$.
Peimbert, Storey \& Torres-Peimbert (1993) extended this interpretation to account for the ORL to CEL abundance discrepancies that they observed for three nebulae. However, as discussed previously, the temperature fluctuation scenario has serious difficulties, and cannot explain, for example, the good agreement between abundances derived from optical and IR CELs for NGC 6543 that was found by Wesson \& Liu (2004). For the current sample, values of $T_{0}$ and $t^{2}$ can be derived from the difference between $T_{\mathrm{e}}([\mathrm{O} I I])$ and $T_{\mathrm{e}}(\mathrm{BJ})$, under the assumption that the $\mathrm{O}^{2+}$ and $\mathrm{H}^{+}$zones are co-extensive (for nebulae where the $\mathrm{O}^{+} / \mathrm{O}^{2+}$ ratio is not small, mainly $\mathrm{H}_{\text {II }}$ regions, the detailed treatment of Peimbert, Peimbert \& Luridiana 2002 should instead be used). The effect this would have on abundance determinations can be calculated as follows. First, the

values of $T_{0}$ and $t^{2}$ can be calculated from the observed values of $T_{\mathrm{e}}([\mathrm{O} I I])$ and $T_{\mathrm{e}}(\mathrm{BJ})$ using the following equations:

$$
\begin{align*}
T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]_{\mathrm{na}}\right)= & T_{0}\left(\mathrm{O}^{2+}\right) \\
& \times\left\{1+\frac{1}{2}\left[\frac{91380}{T_{0}\left(\mathrm{O}^{2+}\right)}-3\right] t^{2}\left(\mathrm{O}^{2+}\right)\right\}, \tag{20}
\end{align*}
$$

$T_{\mathrm{e}}(\mathrm{BJ})=T_{0}\left(\mathrm{H}^{+}\right)\left[1-1.67 t^{2}\left(\mathrm{H}^{+}\right)\right]$.
Then, the average line-emitting temperatures for [ $\left.\mathrm{O}_{\mathrm{III}}\right] \lambda 4959,5007$ and $\mathrm{H} \beta$ can be found using equations (8)
and (9) of Peimbert et al. (2004)

$$
\begin{align*}
T_{[\mathrm{O} \mathrm{~m}]} & =T_{0} \\
& \times\left\{1+\left[\frac{\left(\Delta E / k T_{0}\right)^{2}-\left(3 \Delta E / k T_{0}\right)+0.75}{\left(\Delta E / k T_{0}\right)-0.5}\right] \frac{t^{2}}{2}\right\},  \tag{22}\\
T_{H \beta}= & T_{0}\left[1-(1-\alpha) \frac{t^{2}}{2}\right], \tag{23}
\end{align*}
$$

where $\Delta E=28800 \mathrm{~K}$ for $\left[\mathrm{O}_{\mathrm{III}]} \lambda 4959,5007\right.$, and $\alpha=-0.633$ for $\mathrm{H} \beta$. Finally, once the line-emitting temperatures are known, the factor by which accounting for temperature fluctuations would increase the derived $\mathrm{O}^{2+} / \mathrm{H}^{+}$abundance can be found using equation (15) from Peimbert et al. (2004):

$$
\begin{align*}
\frac{\left(\mathrm{O}^{2+} / \mathrm{H}^{+}\right)_{t^{2} \neq 0}}{\left(O^{2+} / \mathrm{H}^{+}\right)_{t^{2}=0}}= & \frac{T(\mathrm{H} \beta)^{-0.87} T\left(\left[\mathrm{O}_{\text {III }}\right]\right)^{0.5}}{T_{5007 / 4363}^{-0.3}} \\
& \times \exp \left[\frac{\Delta E}{k T\left(\left[\mathrm{O}_{\text {III }}\right]\right)}-\frac{\Delta E}{T_{5007 / 4363}}\right] . \tag{24}
\end{align*}
$$

Table 34 shows the values of $T_{0}$ and $t^{2}$ derived from the observed values of $T_{\mathrm{e}}(\mathrm{BJ})$ and $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]\right.$, the average line-emitting temperatures for $\left[\mathrm{O}_{\mathrm{III}}\right]$ and HI , and the increase $\mathfrak{\Re}$ in the value of $\mathrm{O}^{2+} / \mathrm{H}^{+}$ which would result from including the effect of $t^{2}$ in the abundance determinations. Column 7 gives the observed abundance discrepancy factor, and column 8 gives the ratio of adf $/ \Re$. The nebulae IC 5217 and NGC 6833 are omitted from the table because they have measured Balmer jump temperatures slightly higher than their [ $\mathrm{O}_{\mathrm{III}}$ ] temperatures, and this analysis thus results in an unphysical negative value of $t^{2}$. For the other nebulae, it can be seen that, in almost every case, the increase in the $\mathrm{O}^{2+} / \mathrm{H}^{+}$abundance resulting from the temperature fluctuations implied by $T_{\mathrm{e}}([\mathrm{O} \mathrm{III}])$ and $T_{\mathrm{e}}(\mathrm{BJ})$ is smaller than the observed ORL/CEL discrepancy. This is especially true for the nebulae in the sample showing large values of $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$. For example, $\operatorname{DdDm} 1$ has an $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$ of 12, but even though the Balmer jump temperature is almost 4000 K lower than the [O III] temperature, the implied temperature fluctuations would only increase the $\mathrm{O}^{2+} / \mathrm{H}^{+}$CEL abundance by a factor of 1.9. Similarly, for Vy 2-2,

which also has $\operatorname{adf}\left(\mathrm{O}^{2+}\right)=12$, the temperature fluctuations implied by $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]\right)-T_{\mathrm{e}}(\mathrm{BJ})$ would only increase the $\mathrm{O}^{2+} / \mathrm{H}^{+} \mathrm{CEL}$ abundance by a factor of 2.0. This demonstrates that simple temperature fluctuations cannot be the only cause of the observed abundance discrepancy.

Further evidence that temperature fluctuations alone cannot resolve the observed abundance discrepancies exists for the nebulae for which IR observations exist. As mentioned earlier, the very low excitation energies of IR fine structure lines ( $E_{x} \leqslant 1000 \mathrm{~K}$ ) means that abundances derived from them are insensitive to temperature variations at typical nebular temperatures of $8000-15000 \mathrm{~K}$. Therefore, in the presence of temperature fluctuations they should give higher ionic abundances than optical and UV CELs. Instead, for the four nebulae for which ISO observations were available, very good agreement is seen between abundances derived from optical and IR CELs. For example, Hu 2-1 shows a moderately large $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$ of 6.97 , but the $\mathrm{Ar}^{2+} / \mathrm{H}^{+}$abundance derived from optical CELs is almost identical to the IR CEL abundance, while the $\mathrm{Ne}^{2+} / \mathrm{H}^{+}$and $\mathrm{O}^{2+} / \mathrm{H}^{+}$abundances derived from IR CELs are somewhat lower than those derived from optical CELs, the opposite of what would be expected in the temperature fluctuation scenario. Similarly, for Me $2-2$, the $\mathrm{Ne}^{2+} / \mathrm{H}^{+}$abundances derived from IR and optical CELs differ by only 25 per cent, while the observed $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$ is almost a factor of 3.

The case of NGC 6891 is interesting, as here the temperature fluctuations implied by the observed difference between $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]\right)$ and $T_{\mathrm{e}}(\mathrm{BJ})$ could account for the derived abundance discrepancies. However, looking at the IR CELs, no clear picture emerges. The $\mathrm{Ar}^{2+} / \mathrm{H}^{+}$abundance derived from the [ Ar III] $8.99-\mu \mathrm{m}$ line is 50 per cent higher than that derived from the optical [Ar III] lines, in line with the observed $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$ of 1.52 . However, the [ Ne III] $15.5-\mu \mathrm{m}$ IR line and $\lambda 3868,3967$ optical CELs give $\mathrm{Ne}^{2+} / \mathrm{H}^{+}$abundances which are in excellent agreement.

Finally, the nebula Vy 2-2 has a large $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$ of 11.8 , but in this case the $\left[\mathrm{Ne}\right.$ III] and $\left[\mathrm{Ar}\right.$ III] IR CELs give abundances for $\mathrm{Ne}^{2+} / \mathrm{H}^{+}$ and $\mathrm{Ar}^{2+} / \mathrm{H}^{+}$which are somewhat lower than the corresponding
values derived from optical CELs. This is the opposite of what would be expected if temperature fluctuations were the cause of the observed discrepancy.
The analysis of the current sample points instead towards chemical inhomogeneities within the nebulae. The strongest evidence in favour of this hypothesis is the observed relation between the various temperatures derived from CELs, the hydrogen Balmer jump, He I emission-line ratios and $\mathrm{O}_{\text {II }}$ recombination line ratios, as discussed in Section 3.2. If the observed abundance and temperature discrepancies were caused by temperature variations in a chemically homogeneous nebula, one would expect that the CEL temperature diagnostics would give a temperature weighted towards the hottest regions, while the recombination process temperature diagnostics would all be weighted towards the cooler regions in a similar way. There would be no reason to expect that $T_{\mathrm{e}}\left(\mathrm{O}_{\text {II }}\right)$ would be less than $T_{\mathrm{e}}\left(\mathrm{He}_{\mathrm{I}}\right)$, which would in turn be less than $T_{\mathrm{e}}(\mathrm{BJ})$. This temperature relation is observed in every case in the current sample, and the only obvious way such a temperature relation can be produced is if the lower temperature regions are also enriched in heavy elements and helium.
If knots enriched in heavy elements are present within planetary nebulae, the high CNO abundances within them would result in strong cooling and a low temperature within them. In this case, $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]\right)$ would be most representative of the hot normal component of the nebula, while the temperature given by oxygen recombination lines would be a more direct measure of the temperature in the coldest regions of the nebula. The relative amounts of hydrogen and helium in the warm and cold components of the nebula would determine the temperatures measured from the Balmer jump and He I lines, which would then not necessarily be representative of any real part of the nebula.

Wesson et al. (2003) showed that the H-deficient knots of Abell 30 contain some extremely H -deficient material at very low temperatures. Possible links between A30 and other nebulae in which H -deficient knots are not directly observed are discussed further below.

Figure 8. The ORL/CEL discrepancy for $\mathrm{O}^{2+}$ versus $T_{\mathrm{e}}([\mathrm{O} \mathrm{III}])-T_{\mathrm{e}}(\mathrm{BJ})$.

### 6.3 Correlations with nebular properties

6.3.1 Relation between $\operatorname{adf}\left(O^{2+}\right)$ and the temperature discrepancy

Liu et al. (2001) and Tsamis et al. (2004) have both found that the abundance discrepancy factor for $\mathrm{O}^{2+}\left[\operatorname{adf}\left(\mathrm{O}^{2+}\right)\right]$ is tightly correlated with the difference between $T_{\mathrm{e}}([\mathrm{O} \mathrm{III}])$ and $T_{\mathrm{e}}(\mathrm{BJ})$. The current results follow a similar trend, although with somewhat larger scatter than previously found. The extra scatter is most likely predominantly due to the errors inherent in the measurement of the Balmer jump temperature. Fig. 8 shows $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$ against $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]\right)-T_{\mathrm{e}}(\mathrm{BJ})$ for the current sample, with the dashed line showing the fit found by Liu et al. (2001) to their data. NGC 6891 appears to lie well below the expected line, having a large difference between $T_{\mathrm{e}}\left(\left[\mathrm{O}_{\mathrm{III}}\right]\right)$ and $T_{\mathrm{e}}(\mathrm{BJ})$ but only a $\operatorname{small} \operatorname{adf}\left(\mathrm{O}^{2+}\right)$ of 1.52 . The Balmer jump temperature seems well determined in this object, with good signal-to-noise in the continuum at around $3500 \AA$, and so the temperature discrepancy does not seem to have been overestimated. The abundance determinations also seem very reliable, with the $\mathrm{ORLO}^{2+} / \mathrm{H}^{+}$ abundance based on four detected multiplets which give abundances in excellent agreement with each other.

### 6.3.2 A relation between $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$ and $\mathrm{He} / \mathrm{H}$ ?

Fig. 9 shows $\operatorname{adf}\left(\mathrm{O}^{2+}\right)$ plotted against the total helium abundance $\mathrm{He} / \mathrm{H}$. Although the scatter is large, some evidence for a positive correlation of the adf with helium abundance is seen. The dashed line in the figure represents a linear fit to the data, with log $\operatorname{adf}\left(\mathrm{O}^{2+}\right)=0.446+0.961[\mathrm{He} / \mathrm{H}]$. The correlation coefficient $r=$ 0.25 . A correlation was suggested by Zhang et al. (2004), and could arise because of uncertainties introduced into helium abundance determinations by the presence of H -deficient knots. As helium abundances are derived from recombination lines, the derived helium abundance will be overestimated if H -deficient knots are present as an appreciable amount of helium line emission will arise in the cooler component. Bi-abundance photoionization models by Péquignot et al. (2003) showed that the helium abundance can be overestimated in the presence of a cold H -deficient component. Given that the only helium lines seen in optical spectra are those formed by recombination, the fraction of helium emission from the hot and cold components is unknown. Observations of the nearinfrared Не г $\lambda 10830$ line, which is partially collisionally excited, could lead to a more accurate determination of the true helium abun-

Figure 9. ORL/CEL discrepancy for $\mathrm{O}^{2+}$ versus $\mathrm{He} / \mathrm{H}$.
dance, which is otherwise rendered uncertain by the presence of H -deficient knots.

### 6.4 C/O and N/O ratios

Table 35 shows the C/O and N/O elemental ratios derived from ORLs and from CELs for the sample nebulae. In most cases the ORL and CEL ratios are quite similar, but in some cases large discrepancies exist. For N/O, a few objects show a much larger N/O ratio from ORLs than from CELs. This discrepancy is present in the $\mathrm{N}^{2+} / \mathrm{O}^{2+}$ ratios, the dominant ions of N and O . If the enhanced ORL abundances seen in the sample are due to H -deficient regions within the nebula, the higher ORL N/O ratios might point to a different chemical composition for these regions, and may suggest that they are highly processed material ejected by the central star.

Kingsburgh \& Barlow (1994) define a Type I planetary nebula as one in which dredged-up carbon has been converted by envelope

Table 35. $\mathrm{C} / \mathrm{O}$ and $\mathrm{N} / \mathrm{O}$ ratios from ORLs and CELs in the sample nebulae.

| Nebula | C/O (CELs) | C/O (ORLs) | N/O (CELs) | N/O (ORLs) |

burning into nitrogen, resulting in an N/O ratio greater than the $(\mathrm{C}+\mathrm{N}) / \mathrm{O}$ of $\mathrm{H}_{\text {II }}$ regions within the host galaxy of the planetary nebula. For our Galaxy, $(\mathrm{C}+\mathrm{N}) / \mathrm{O}=0.8$, and so Me $2-2$ qualifies as a Type I planetary nebula according to both CEL and ORL N/O ratios. DdDm 1, M 1-73, M 3-27 and NGC 6807 have ORL ratios which imply that they are Type I, but have non-Type I CEL ratios.

### 6.5 Possible origins of inclusions

Wesson et al. (2003) showed that the centre of the knots in Abell 30 must consist of extremely hydrogen-deficient material at very low temperatures, and subsequent three-dimensional photoionization modelling of the knots (Ercolano et al. 2003) showed that this was a physically plausible situation, with the very high CNO abundances in the core of the knot strongly cooling the material and giving rise to the very low temperatures of the ionized gas. There is very good evidence from the sample of nebulae analysed in this paper that hydrogen-deficient material exists in many if not all planetary nebulae. Such material may have a similar origin to the knots of Abell 30.

Wesson et al. (2003) discussed some of the problems with the born-again theory of Iben, Kaler \& Truran (1983). Most importantly, the born-again theory predicts carbon-rich knots, whereas both CELs and ORLs give $\mathrm{C} / \mathrm{O}<1$ for the knots in Abell 30. In the current sample, 17 out of 23 nebulae also have a C/O ratio less than unity, with only one (Sp 4-1) having a ratio substantially greater than 1 , indicating that an ejection of material in a very late helium flash is unlikely to be the origin of H -deficient regions in most planetary nebulae.
The collinearity of the two polar knots with the central star in A30 is also very hard to explain in a single star scenario, and suggests instead an accretion disc within a double star system. Recently, De Marco et al. (2004) have suggested that a large fraction of planetary nebula central stars may be spectroscopic binaries. They found radial velocity variations in 10 out of 11 planetary nebula central stars analysed, although without confirming that the variation was periodic. If a majority of planetary nebulae contain a double star system, then ejection of material from an accretion disc giving rise to hydrogen-deficient material could be the mechanism behind the observed abundance discrepancies.

A better understanding of the nature and origin of the H -deficient regions would result from much deeper and higher resolution spectra than have been analysed here, but it may be that the knots are so small that they will never be resolved.

## ACKNOWLEDGMENTS

Table A1. Optical line lists.

## APPENDIX A: OPTICAL LINE LISTS

Table A1 contains the line lists derived from the INT data for the sample nebulae. The columns contain, from left to right, the observed wavelength, the measured flux normalized to $F(\mathrm{H} \beta)=100$, the dereddened flux, ionic identification, multiplet number, lower term and upper term of the transition, and statistical weights of the lower and upper levels.

Table A1. Optical line lists for the sample nebulae. (This is only a sample of this table: the full version is available online as supplementary material.)

## APPENDIX B: ULTRAVIOLET AND INFRARED LINE LISTS

Table B1. Infrared line fluxes for the nebulae observed with the $I S O$ satellite. $F(\lambda)$ is in units of $10^{-13} \mathrm{erg} \mathrm{cm}^{-2} \mathrm{~s}^{-1}, I(\lambda)$ is normalized to $I(\mathrm{H} \beta)=100$ using $\mathrm{H} \beta$ fluxes from Cahn et al. (1992). Critical densities are taken from Rubin (1989).
