ABSTRACT

Objectives Large differences exist in the burden of cardiovascular disease (CVD) between Russia and Western European countries including Norway. Obesity prevalence may contribute to the differences. We investigated whether difference in the level of adiposity, assessed using body mass index and waist-to-hip ratio (WHR), could explain intercountry differences in the burden of carotid plaque, a measure of atherosclerosis, in the populations.

Design Cross-sectional analysis. Logistic and linear regression models were used.

Setting We used population-based cross-sectional Know Your Heart (KYH) study in Russia and the Tromsø 7 study (Tromsø 7) in Norway.

Participants 3262 and 1800 men and women aged 40–69 years in KYH and Tromsø 7, respectively.

Primary and secondary outcome The presence of carotid plaques and plaque score assessed using ultrasound.

Results The presence of carotid plaques and plaque score were higher in KYH than Tromsø 7 regardless of age group and sex. A positive association between carotid plaque burden and adiposity was found (OR of having at least one plaque per SD in WHR 1.18 (95% CI 1.06 to 1.31) for men; 1.15 (1.06 to 1.25) for women)) adjusted for age, smoking and education in a pooled analysis of the two studies. There was little evidence of the interaction between study and adiposity. These effects did not differ between the two studies. However, neither adiposity nor CVD risk factors (smoking, systolic blood pressure, cholesterol, glycosylated haemoglobin) explained the higher carotid plaque burden in KYH compared with Tromsø 7.

Conclusion Adiposity, especially abdominal adiposity, is a risk factor for carotid plaque in Russia and Norway, although neither adiposity nor established CVD risk factors explained the higher plaque burden in Russia. To reduce the CVD burden in Russia, beyond prevention and treatment of adiposity, further research is required to understand why Russia has a high burden of atherosclerosis.

INTRODUCTION

The mortality rate from cardiovascular disease (CVD) has been decreasing for many years in Western Europe, and more recently, in Eastern Europe. However, rates vary substantially between countries, with Russia having one of the highest CVD mortality rates, although it has been declining since 2005. In 2012–2016, the CVD mortality rate at working ages in Russia was eight times higher than that in Norway. These premature deaths contribute to the relatively low life expectancy for such an industrialised country. However, the reasons for this very high CVD burden in Russia remain unclear. It appears that the differences in conventional CVD risk factors such as smoking, blood pressure and cholesterol levels do not explain this difference well.

The increase in obesity over the past decades is a growing concern worldwide, including in Russia and countries of Western
Europe, 7 and has an effect on mortality levels. 8 In addition to general obesity, however, the extent of abdominal obesity is likely to be important as there is evidence that it is more strongly associated with CVD events than general adiposity assessed using body mass index (BMI). 3–11 However, data on population levels of abdominal obesity (such as waist-to-hip ratio (WHR)) is far less common than for BMI, in Russia as well as in other countries. To the best of our knowledge, the contribution of general or abdominal obesity to the gap in CVD burden between Russia and Western European countries has not been investigated in spite of increasing importance of obesity as a CVD risk factor.

Carotid plaque, representing an advanced stage of atherosclerosis, is predictive of future CVD events. 12 Carotid atherosclerosis may be easily and reliably detected using an ultrasound examination making carotid plaque a good surrogate marker of atherosclerotic CVD burden in large-scale epidemiological studies. Our previous study using Tromsø Study fifth survey has shown that abdominal adiposity was more closely associated with carotid plaque burden than BMI. 13 Furthermore, WHR showed the larger effect size than waist circumference (WC) and waist to height ratio.

We used data from two studies from general populations with very different CVD mortality in Europe: Know Your Heart (KYH) study in Russia and Tromsø Study seventh survey (Tromsø 7) in Norway. Our aims were: (1) to compare general and abdominal adiposity levels, represented by BMI and WHR, respectively, and the burden of carotid plaque in Russia with those in Norway, a low CVD mortality country; (2) to investigate the association of BMI or WHR with carotid plaque in both populations and (3) to investigate whether BMI or WHR or other factors can explain difference in carotid plaque burden between the two populations.

METHODS
Study design and participants
We used data from two studies; the KYH study from Russia and the Tromsø 7 study from Norway. Researchers from the two studies worked together at the design stage to align aspects of the study protocols used, including the detailed standard operating procedures for carotid ultrasound examinations as described elsewhere. 4 14 15

KYH is a population-based cross-sectional study of 4500 women and men aged 35–69 years conducted between 2015 and 2017 in two Russian cities: Novosibirsk and Arkhangelsk. The details of KYH have been described elsewhere. 4 Briefly, participants were recruited from a random sample of the population stratified by age and gender, derived from the list of the Territorial Health Insurance Funds. Trained interviewers visited the addresses on the list and identified residents of the target age and sex. Information on sociodemographic characteristics, CVD risk factors and medical history was collected using structured questionnaires completed on tablet computers. At the end of the interview, participants were invited to have a comprehensive examination including anthropometric measurement, blood sampling, and carotid ultrasound 1 or 2 weeks later. Response rates for initial interview were 53% and 27% in Arkhangelsk and Novosibirsk, respectively. Of those interviewed 89% attended the subsequent medical examination. All participants of the medical examination provided signed informed consent.

The Tromsø Study is an ongoing population-based study in Tromsø municipality, North Norway and consists of seven surveys from 1974 to 2016. 16 In the seventh wave (Tromsø 7), all residents in Tromsø aged 40 years and older were invited to participate. The questionnaires were completed, a brief physical examination was carried out and biological samples were taken. A random sample, including previous participants, was invited to a second visit to undergo more comprehensive medical examinations. A total of 21 083 attended the first visit and the response rate was 65%. A total of 4153 participants were invited to a carotid ultrasound examination and 2974 (71.6%) attended.

In the two studies, participants aged between 40 and 69 years (n=5782) were eligible for the present study. We excluded participants with missing data on all adiposity measures (n=42), and potential confounders and mediators (n=678), leaving 3262 participants from KYH (57% women) and 1800 from Tromsø 7 (55% women) for the analyses.

Assessment of anthropometric measures and other CVD risk factors
In both studies, height and weight were assessed by trained staff using standard methods (see online supplementary material). BMI was calculated by dividing weight in kilograms by squared height in metres. WC was measured at a different site in the two studies: in KYH WC was measured at the narrowest part of the trunk to the nearest millimetre using a tape measure while in Tromsø 7 WC was measured at the level of the umbilicus. Hip circumference was measured at the widest part in both studies. To ensure WC was comparable between the two studies, WC in Tromsø 7 was converted to the narrowest waist using a conversion equation by Mason and Katzmarzyk. 17 Among anthropometric measures of abdominal adiposity WHR was selected because it has been found to be strongly associated with CVD events. 10 11 18

Information on age (5-year categories), smoking (current smoker, ex-smoker, never-smoker), educational attainment (higher education: yes/no) and medical history of diabetes mellitus (DM) (yes/no) were collected through face-to-face interview in KYH and self-administered questionnaire in Tromsø 7. The assessment of systolic blood pressure (SBP) and other laboratory data are described elsewhere (see online supplementary material). 4

Ultrasound examination

Technical details of the examination protocols have been described elsewhere. Briefly, both carotid arteries were scanned for carotid plaques in the common carotid artery (CCA), bifurcation and internal carotid artery (ICA) using a Vivid Q (GE Health care) with 6–13 MHz linear transducers in KYH and Vivid 7 (GE Health care) with a linear 12 MHz transducer in Tromsø 7 (see online supplementary material). Carotid plaque was defined according to the Mannheim Consensus as a focal structure encroaching into the arterial lumen by at least 0.5 mm, or having a thickness ≥50% greater than the surrounding intima–media thickness (IMT), or IMT >1.5 mm as measured from the media–adventitia interface to the intima–lumen interface.19

To evaluate the burden of carotid plaque, we created a cumulative plaque score by assigning a score of one for the presence of one or more plaques in each of the six carotid segments (CCA, bifurcation and ICA of each carotid artery) with a maximum possible score of 6 for each individual.

Statistical methods

Analyses were conducted stratifying by sex a priori. Two outcome measures were used: the presence of plaques as a binary outcome and plaque score. As exposures, BMI and WHR were used to represent general and abdominal adiposity, respectively. To enable direct comparison of the magnitude of the effects of BMI and WHR, sex-specific adiposity z-scores standardised to Tromsø 7 participants were created by subtracting the mean and dividing by the SD of each measure in Tromsø 7.

Variables included in the model were selected from established CVD risk factors.20 Age, smoking and education were considered a priori confounders while SBP, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, glycosylated haemoglobin (HbA1c) and medical history of DM were considered as potential mediators. Sex-specific linear and logistic regression models were used to investigate the associations of each adiposity with plaque score and presence of plaques respectively. A series of models were fitted that were specific to each sex and study (four in all). Model 1 adjusted for age (5-year age groups). Model 2, our main model to elucidate the association between adiposity and plaque burden, further adjusted for potential confounders. Model 3 further adjusted for potential mediators to see to what extent the association was mediated by these factors. These analyses were conducted using the data from each study and the pooled data from the two studies after checking for interaction with study. This was done by adding an interaction term between study and adiposity using pooled data: testing for statistical significance using likelihood ratio tests for logistic regression and Wald tests for linear regression.

Finally, to estimate the difference in plaque burden between the two studies, we applied a similar set of models as already described to the pooled data using a binary indicator for study. The associations between each study and plaque burden (the presence of plaques, plaque score) were estimated using logistic and linear regression, respectively. To look at adjusted difference in plaque burden between the two studies, three similar models adjusted for age, confounders and mediators, were applied without adjustment for adiposity. We then separately added each adiposity measure to these models to estimate the effect of adiposity on between-study difference in carotid plaque burden.

STATA V.15 (StataCorp) was used for all the analyses.

RESULTS

Baseline characteristics of participants

Table 1 shows participants’ baseline characteristics. The age-adjusted prevalence of current smoking in men was much higher in KYH than Tromsø 7 but similar for women. However, female never smokers made up two-thirds in KYH but just over a third in Tromsø 7. Mean SBP was considerably higher in KYH than in Tromsø 7.

Adiposity

Both BMI and WHR were higher for women in KYH than those in Tromsø 7. Adiposity z-scores for BMI and WHR for the KYH women standardised to the Tromsø 7 population adjusted for age were 0.58 (95% CI 0.49 to 0.68) and 0.84 (95% CI 0.76 to 0.92), respectively. However, adiposity did not differ between men in the two studies.

Prevalence of carotid plaques

The prevalence of carotid plaques and the mean plaque score increased with age in both women and men (table 2). The burden of plaques was consistently higher in KYH than Tromsø 7 in both sexes.

The association between carotid plaque burden and adiposity: a pooled analysis of the two studies

Table 3 shows the ORs for having at least one carotid plaque per 1SD increase in each adiposity measure by sex from the pooled analysis. We also analysed the two studies separately, but only presented the result from the pooled data based on the test of interaction described below. The two adiposity measures were not adjusted for each other.

</table>

Data are presented as percentages for binary variables and as mean values (SD) continuous variables, except for age, triglycerides which are presented as median (IQR).

*Analyses were restricted to participants aged between 40 and 69 years with information on all covariates.

†All comparisons age adjusted.

‡WC in Tromsø 7 assessed at the level of the umbilicus was converted to the narrowest WC so that it can be comparable with WC in KYH. WHR in T7 are calculated using converted WC.

BMI, body mass index; HbA1c, glycated haemoglobin; HDL, high-density lipoprotein; LDL, low-density lipoprotein; SBP, systolic blood pressure; WC, waist circumference; WHR, waist-to-hip ratio.

After adjustment for confounders (model 2), there was evidence of association between all adiposity measures and the presence of plaques except for BMI in women. WHR showed larger standardised ORs (women 1.15 95% CI 1.06 to 1.25, men 1.18 95% CI 1.06 to 1.31) than BMI. After further adjustment for cardiometabolic mediators (model 3), all ORs decreased substantially.

Table 4 shows the difference in plaque score per 1 SD increase in each adiposity measure. In women, adiposity was associated with an increase in plaque score. Again, WHR showed a larger effect size (increase per 1SD change 0.109 95% CI 0.070 to 0.147) than BMI. Additional adjustments for cardiometabolic mediators reduced both effect sizes substantially. For men, there was no evidence of an association of BMI and WHR with plaque score.

Tests for interaction between study and adiposity were not statistically significant except for the association between BMI and the presence of plaque in women and that between WHR and the plaque score in women, suggesting that there is little evidence that the association between adiposity and plaque burden differs between the two studies (online supplementary table 1, online supplementary figure 1A, B).

*Adjusted for categorical age (5-year interval). KYH, Know Your Heart.

Between-study differences in carotid plaque burden and the effect of adiposity

Figure 1 compares the carotid plaque burden between the two studies with and without adjustment for adiposity. Without adjustment for adiposity measures, the OR for having at least one plaque in KYH compared with Tromsø 7 was 1.97 (95% CI 1.62 to 2.38) in women and 2.78 (95% CI 2.21 to 3.49) in men (figure 1A, online supplementary table 2A model 2). Further adjustment for BMI or WHR separately had only a small effect on this OR for both men and women (figure 1A). The between-study difference remained large and statistically significant after further adjustment for cardiometabolic mediators (figure 1A, online supplementary table 2A model 3).

Similarly, without adjustment for adiposity, participants in KYH had a higher mean plaque score than those in Tromsø 7 by 0.51 (95% CI 0.42 to 0.60) for women and 0.89 (95% CI 0.77 to 1.00) for men; these estimates decreased slightly for women and hardly changed at all for men with further adjustment for adiposity (figure 1B, online supplementary table 2B). The between-study difference remained significant after further adjustment for cardiometabolic mediators (figure 1B, online supplementary table 2B model 3).

**DISCUSSION**

There was evidence of positive associations between adiposity, especially abdominal adiposity, and carotid plaque burden, but no convincing evidence that the strength of these associations differed between the two studies. These associations were largely mediated by cardio-metabolic CVD risk factors. However, neither adiposity nor the confounders and potential mediators explained the substantially greater burden of plaque in the KYH study in Russia compared with the Tromsø 7

Given the similar adiposity level between KYH and Tromsø 7 among men, it is not surprising that higher plaque burden in men in KYH is not explained by adiposity. However, even among women whose adiposity level was considerably higher in KYH than Tromsø 7, the adjustment for adiposity had little impact on the interstudy difference in carotid plaque burden. Furthermore, additional adjustment for CVD and metabolic risk factors such as smoking, SBP and cholesterol level slightly reduced this interstudy difference, but the between-study difference remained for both men and women, suggesting that there are other determinants of higher carotid plaque burden in a population in KYH. This is consistent with previous studies conducted 20 or more years ago, showing that differences in traditional CVD risk factors did not fully explain the high CVD burden in Russia compared with Western European countries.5 6

More advanced subclinical atherosclerosis in participants in KYH compared with Tromsø 7 is in keeping with the higher CVD mortality rate in Russia than Western European countries.4 21

The development of coronary artery disease and atherosclerotic plaque is a gradual process that occurs across the life course.22 The extent to which single cross-sectional measurements of risk factors such as blood pressure and smoking can capture the full impact of these risk factors on the burden of carotid plaque is therefore questionable. In making the sort of comparisons between populations that are the focus of this paper, therefore, it could be that we are underestimating the potential contribution of these risk factors to differences in plaque burden, particularly if risk factor profiles have been changing.

One potential determinant of high CVD risk in Russia that we have not included is alcohol which has been shown to be related to mortality from CVD.23 Vikhireva et al added hazardous alcohol consumption to the high-risk version of Systematic COronary Risk Evaluation (SCORE) to see whether this modified model improved prognostic performance of SCORE for future CVD events in the Russian population. However, this modification did not improve the prediction of CVD events24 although the study had limited follow-up and relatively small numbers.
of events. Moreover, it excluded as an outcome alcoholic cardiomyopathy that contributes to the high CVD mortality in Russia involving processes other than atherosclerosis. Differences in treatment and access to the medical facilities between Western Europe and Russia is likely to partly account for the higher CVD mortality rates in Russia, but it is unlikely that differences in treatment could account for the differences in subclinical atherosclerosis in a population-based samples. Furthermore, the treatment and access to appropriate medical care have been improving rapidly in Russia, especially in large cities, so this is likely to be a less important factor in the future. Identification of the determinant(s) of advanced subclinical atherosclerosis in Russia will be important to target interventions to reduce CVD burden.

There was evidence of positive associations between adiposity and plaque burden in both studies emphasising the importance of the control of adiposity, especially abdominal adiposity, to curb the CVD burden in both countries. The prevalence of obesity in Russia has been increasing, with the notably high level among women being of particular concern. Another important implication of our findings is the importance of the control of cardiovascular and cardiometabolic mediators. The associations between adiposity and carotid plaque burden were largely mediated by SBP, cholesterol level and HbA1c. The effective control of these traditional risk factors will mitigate the negative effect of adiposity.

This study is the first, to our knowledge, to bring together data from a high and relatively low CVD mortality country to investigate the association of adiposity with carotid plaque, and also the extent to which this can explain differences in the burden of carotid plaque between the two populations. Moreover, this was done using ultrasound examination protocols that were aligned between the two studies. No previous studies have compared imaging of atherosclerotic changes in general populations between Russia and Western countries. However, our investigation has some limitations. First, the anthropometric measures we used are crude measures of visceral adiposity. However, estimation of visceral adipose tissue using MRI and CT is resource demanding and logistically difficult in large epidemiological studies. Second, WC was measured differently between the two studies. Although the conversion of WC was made using a conversion equation, this did not allow for individual variability. Standardisation of the protocol of WC measurement would be important in future studies. Third, we did not include alcohol in our regression models, although it is likely to play an important role in CVD mortality in Russia. This is because alcohol consumption in the two study populations was not directly comparable. Finally, as always, caution must be exercised in generalising to the national situation the results we have obtained from the two cross-sectional studies of selected groups in two cities in Russian and one in Norway city.

Overall, our findings have two implications with respect to tackling the high CVD burden in Russia. First, although adiposity failed to explain higher plaque burden in Russia compared with Norway, adiposity, especially abdominal adiposity, appeared to contribute to an increase in carotid plaque burden through cardiometabolic mediators such as blood pressure and cholesterol. The reduction of adiposity level will be important to avoid further CVD burden in addition to the control of cardiometabolic mediators. Second, our findings suggest that there are other unidentified risk factors that determine the higher carotid plaque burden in Russia compared with Norway. Further studies will be needed to identify them.
