A Systematic Literature Review of Reviews on the Effectiveness of Chlamydia Screening

Abstract

_Chlamydia trachomatis_ is the most common bacterial sexually transmitted infection, causing significant morbidity and economic burden. Strategies like national screening programs or home-testing kits were introduced in developed countries, yet their effectiveness remains controversial. This systematic review examined reviews on chlamydia screening interventions to assess their effectiveness and the elements that contribute to their success to guide public policy and future research. The review assessed English material published after year 2000 in PubMed, Cochrane Library, the British Nursing Index, Medical Database, and Sociological Abstract, in addition to WHO Global Health Sector Strategies, the European Center for Disease Prevention and Control guidelines, and PROSPERO. Systematic reviews focused on chlamydia screening interventions were included. Using the socio-ecological model, we examined the levels of interventions that may affect the uptake of chlamydia screening.[10] Systematic review were included. Self-collection in home-testing kits significantly increased screening among females 14-50 years of age. Interventions utilizing reminders had promising results in increasing re-screening rates. At the organizational level, using electronic health records and not creating additional costs facilitated testing. At the community level, outreach interventions in community/parent centers and homeless shelters reached high participation rates. At the policy level, interventions with educational and advisory elements could result in significant improvements in screening.

Introduction

*Chlamydia trachomatis* is the most common bacterial sexually transmitted infection (STI) and causes significant morbidity and economic burden globally. There are approximately 131 million new cases occurring in individuals aged 15-49 years annually, with an incidence rate of 38 per 1000 females and 33 per 1000 males. Among the non-viral STIs, chlamydia is the most costly infection, which costs the US healthcare system approximately US$516 million annually.

The majority of chlamydia infections are asymptomatic, only 30% of women and 10% of men develop symptoms. Therefore, infected people often do not seek testing and are unaware of their infection. Uncomplicated chlamydia infection symptoms include abnormal vaginal discharge and post-intercourse bleeding among women. It should be noted that *chlamydia trachomatis* is an important cause of pelvic inflammatory disease (PID). A community-based study found that the 1-year incidence of PID among women with untreated chlamydia infection was about 10%. Other reproductive sequelae of chlamydial PID include infertility, ectopic pregnancy and chronic pelvic pain. The reported infertility rate after one episode of PID was 8% and it increases to 38% after three PID episodes. Chlamydia infection is also associated with negative psychosocial impact and poor sexual quality of life in young women.

Chlamydia is curable; so early detection and treatment would minimize the risk of these serious long-term diseases and reduce further transmission.

To reduce chlamydia disease burden, control strategies such as national screening programs, opportunistic screening for women <25 years, and targeted screening have been promoted in developed countries. England initiated their National Chlamydia screening program where free screening is provided in settings such as community sex clinics, general practices, and community pharmacies. For sustainable benefits to occur, screening and follow-ups should be regular. Such requirements may be difficult as the target population must utilize health service regularly and health providers must offer the tests at appropriate intervals. Administrative systems also need to track individuals who attend various health venues. The introduction of quick and non-invasive testing methods such as nucleic acid amplification tests (NAATs) has allowed testing to be done out-of-clinic and more convenient; nonetheless, chlamydia testing rates remain sub-optimal. Factors that lead to continued low screening rates include hesitation and embarrassment from patients and limited understanding and training amongst healthcare providers. The increase of the uptake of chlamydia screening is needed to diminish the negative impacts of chlamydia infections on our society.

There is an abundance of literature related to chlamydia screening. Certain interventions target patients while others target the healthcare providers, and the delivery format of the interventions also varies. With the myriad of interventions, it is difficult to determine which interventions are effective and there is a lack of consensus on the most effective way to increase chlamydia screening. We considered that a systematic review of review articles, comprising a comprehensive examination of the current state of knowledge about chlamydia screening, is needed in order to guide our public health policy as well as further interventions and research in the area. This systematic review will review systematic reviews focused on chlamydia screening interventions with the aim of identifying factors that facilitate increased chlamydial screening uptake.
Methods

We conducted this systematic review of reviews in accordance with the guideline of the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA). The systematic review protocol was registered on the PROSPERO database (registration number: CRD42018085514).

Information Sources and Search strategy

Five databases were used to identify review articles that have evaluate chlamydia screening intervention. They are PubMed, Cochrane Library, the British Nursing Index, Medical Database, and Sociological Abstract via ProQuest. Searches in PubMed were conducted with the Medical Subject Headings (MeSH) terms of “Chlamydia” and “mass screening” then filtered for systematic reviews and meta-analysis. In the Cochrane library, the advanced search function was used for the key words “chlamydia” and “screening”. In ProQuest, advanced search was carried out for the key words “chlamydia”, “mass screening”, and “systematic review”.

Besides, the reference lists of the WHO Global Health Sector Strategies and the European Center for Disease Prevention and Control guidelines were screened. PROSPERO database was also searched. Experts in our network were approached for suggestions of relevant papers.

Inclusion Criteria

We only included systematic reviews and meta-analysis published in English after 2000 because NAAT diagnostic technology was not introduced until then. Interventions must focus on Chlamydia screening (studies regarding STI screening were accepted as long as chlamydia is included). Interventions must have one or more of these outcome measures: number of chlamydia tests, testing rate, retesting rate, and/or treatment rate of chlamydia.

Screening

One author (SL) screened the titles and abstracts and two authors (SL and EC) independently conducted full text screening and data extraction. Discrepancies were resolved through discussion and input from another author (WC).

Data Extraction

A raw data extraction sheet was created and included information such as target populations, settings, type of testing, number of people tested, prevalence, number of people treated, effectiveness, and barriers. The data extraction summary sheet is available in the appendix.

Quality Assessment

The quality of the included papers was assessed using the validated scale Assessment of Multiple Systematic Reviews (AMSTAR). The AMSTAR provides a 16-item checklist on the quality of systematic review methodology.
Analysis

The socio-ecological model was used to organize the interventions (Figure 1). The socio-ecological model is a systems model with multiple levels of influence including interpersonal, organizational, community, and policy levels. Interventions based on the individuals’ characteristics aim to influence their knowledge, attitude, and beliefs towards a health behavior. Interventions at the interpersonal level influence social norms to overcome individual barriers. Involved parties include friends, family, community health workers, and health service providers. Interventions in the organizational level involve healthcare systems, health departments, and health clinics. Interventions in the community level try to leverage resources and encourage the participation of community-level institutions. Interventions at the policy level aim to create systemic changes. Health intervention developers often utilize this model to ensure that the intervention accounts for these interwoven bands of influence to result in the greatest impact.

Results

200 studies were identified in the initial search of the databases and 5 studies were identified through other sources, as previously described. During the title screen, 148 studies were excluded because their titles did not mention that it was a systematic review, was not about sexually transmitted infections, or was not in English. During the abstract screen, 33 studies were excluded if the abstract did not mention chlamydia screening. 24 reviews were assessed by full text screen in which three was excluded to result in the final inclusion of 19 reviews. One study was excluded because it described itself as a review but was ultimately not a systematic review. Two studies were excluded because it was regarding diagnostic tools for detecting chlamydia. Two studies were excluded because it was about rescreening (Figure 2).

Quality Assessment

Papers were marked out of a score of 16 and categorized into groups of low quality (0-5.5 score), medium quality (6-11.5 score), and high quality (12+ score). Eleven systematic reviews were of low quality, nine of medium quality, and one of high quality. Twelve papers did not explain their selection of study design for inclusion. Two papers provided a list of excluded studies with justifications and one provided the list without justifications. One review reported funding information. Four utilized a satisfactory risk of bias technique for included studies while one obtained a “partial yes” in this criterion.

Individual and Interpersonal Levels

The systematic review by Chacko et al. focused on both health provider-based and client-initiated chlamydia screening practices in asymptomatic young women in the United States. Based on the evidence gathered and evaluated, the review revealed that the screening of sexually active women under the age of 20 was the top priority. However, the authors of the review pointed out that it was challenging to evaluate the effectiveness of health provider-based screening programs because of the large size of program, variations in prevalence rates in
populations targeted and the criteria used to determine effectiveness. Besides, the review found that there was a marked absence of programs and no publication describing intervention to foster client-initiated screening behaviors among asymptomatic young women in the United States, despite of the CDC’s recommendations.

A systematic review by Odesanmi et al. compared the screening uptake levels of home-based self-sampling and clinic-based specimen collection for *Chlamydia trachomatis* in females aged 14-50 years old. The review only included randomized control trials (RCTs). Self-collection is where people bring a kit home and send the sample to a testing facility without needing to attend a health facility. The review supported the use of home sampling to increase screening uptake but cost-effectiveness should be further investigated. Furthermore, the review reported a significant preference for self-collection compared to clinic based testing. Another systematic review only focused on the home-based screening strategy and divided home-based screening into seven groups according to test kit and specimen delivery methods. The highest median specimen return rate was in outreach programs in which participants were approached at home with immediate collection of specimens (96.5%), programs providing home testing kits only on invitation acceptance (78.9%), home testing kits sent along with an invitation (32.9%), home testing kits requested without an invitation (31.8%), home testing kit offered in person (21.4%), and home testing kits picked up at specific locations (18.6%). However, the interventions targeted a wide range of target populations hence comparison between each program may not be valid. Nonetheless, this review shows that self-collection programs have been conducted in a variety of countries and with different delivery methods, suggesting that home-based testing is a feasible and acceptable chlamydia screening method. However, further studies regarding its cost-effectiveness are needed.

**Organizational Level**

A systematic review by Taylor et al. categorized screening interventions into levels of effectiveness as measured by the absolute difference in percent of target population screened. Effective and low-moderate costs interventions ($USD<1,001-10,000) utilized patient reminder strategies such as postcards and calls. Effective and high costs ($USD$10,000-100,000) interventions involved dedicated screening staff. The authors concluded there is a variety of effective and cost-effective screening interventions.

Interventions targeting females resulting in significant increases in screening rates include linking screening to pap smears (6.9% vs. 4.5%), computer alerts for doctors (15.5% vs. 12.4%), and free sexual health consultation (16.8% vs. 13.2%). Screening program initiation is associated with chlamydia infection reduction and screening women with a certain range of risk factors reduces PID incidence for 1-year. Challenges in implementing healthcare provider screening interventions include lack of protocols of urine sample obtainment, insufficient knowledge about chlamydia and urine-based tests, and reluctance of staff to be engaged in adolescent STI screening. The effectiveness and feasibility of screening for chlamydia in emergency departments has also been examined. Prevalence of emergency department patients
was high (9.1-9.5%). Barriers include finding a location for screening in the emergency department, clinician’s willingness and time constraints, and availability of other staff.

The systematic review by Gudka et al. examined pharmacy-based screening interventions. Return rates were high in studies with 47% in England, 63.9% in Scotland, 28% in Australia, and 38% in the United States. Major barriers of pharmacy-based screening included having to return the specimen to designated sites and lack of privacy for patients and increased workload or feeling uncomfortable when offering the test, and lack of in store advertising for pharmacists. The major benefits for patients included convenience, anonymity, and no need for appointment, affordability, shorter waiting times, and friendly non-judgmental attitude of pharmacists. It was concluded that chlamydia screening in community pharmacies were feasible and could be a convenient option.

**Community Level**

In a review by Bernstein et al., screening interventions in non-clinic settings were examined. The review revealed that high number of tests could be carried out in correctional settings and identified a large amount of asymptomatic infections. The total number of people approached was unavailable but high prevalence was found amongst adolescent girls in juvenile detention centers in Southern City (24.7%), Georgia (16.8%), and California (13.0%). Other community-based screening included homeless shelters, family court, and mobile van but they identified few new infections. High chlamydia prevalence was also found when screening in educational settings. The prevalence was 12.4% for males and females in a classroom-based strategy, 18.8% for females in school-based health clinic, 15.6% for male and females in other school locations, and 15.0% in clinical session screening. Chlamydial screening in educational settings is a feasible approach with a range of delivery methods identifying large numbers of infected adolescents.

In the systematic review by Hengel et al., outreach interventions targeting young people aged 15-29 years, men who have sex with men, and sex workers were identified. Amongst the outreach settings, the highest participation rate was in community venues such as community centers, parenting centers, and homeless shelters (81.4%) and social venues such as sport venues or bars (80.4%). In interventions targeting adolescents and young adults, Gold et al. found a high testing rate (75.2%, tests = 92) in a screening program in a football club changing room in Australia. High testing rates were also found in community venues targeting dropouts, new immigrants, and vocational school students in the Netherlands (79.6%, tests = 74). Low participation rates were identified in street and public community areas (median=23.9%, n=3) and sex venues (10.4% and 24.3%, n=2). The authors concluded that chlamydial outreach programs are able to result in high participation rates but with limited reach. Settings that resulted in higher participation rates seem to be less public.

**Policy Level**

*Education and advisory*
In the systematic review by Ginige et al., a cluster RCT assessing the effectiveness of an educational package in general practitioners (GPs) in Belgium was analyzed. The target population was females aged below 35 years old. The intervention included a stimulated consultation and text messages regarding communication skills. The intervention group performed significantly better by carrying out more screening (median 6 patients per GP vs. 3 patients per GP, \( p = 0.035 \)). Another study investigated the effectiveness of having a health advisor in primary healthcare centers to increase awareness of chlamydia and to train the staff in Scotland. Testing rates in the intervention centers was significantly higher than those in the control (120%, vs 11%, \( p<0.001 \)). However, the denominator value indicating the number of patients seen was missing in the primary paper.

Allison et al. carried out a study regarding the effectiveness of an internet-based continuing medical education (CME) to increase chlamydia screening by primary care physicians in the US. The CME course consisted of 4 modules over 3 months. The chlamydia screening rates for before, during and after the intervention were 16.2%, 13.3%, and 15.5% for the intervention group respectively vs. 18.9%, 13.0%, 12.4% for the control (\( p=0.044 \) for post-intervention differences).

**System-level changes in clinical practice**

In the same systematic review by Ginige et al. a RCT assessing the effectiveness of a multi-phased intervention aimed to result in system-level changes in clinical practice regarding chlamydia screening was analyzed. The intervention consisted of four stages where the first stage was engagement with the organization’s leaders to investigate the discrepancy between current and best practice. The second stage involved the formation of adolescent care teams, a model for practice change, and a staff toolkit. The third stage involved monthly meetings between clinic team members. The final stage developed performance indicators. The intervention clinics saw a significant number of females ages 14-18 screened as compared to the control clinics (478 of 1017 vs 203 of 1194, \( p<0.001 \)). The authors concluded that there is a variety of ways to increase chlamydia screening but more RCTs are needed.

**Discussion**

Adolescent girls have always been the targets of screening programs but high chlamydial prevalence was also found in adolescent boys. Screening all or only high-risk adolescents have strong implications on monetary and human resources. Even if mass screening for adolescents is implemented, it is difficult to ensure the acceptance of the target population. The US Center of Disease Control (CDC) has recommended annual screening of women under age 26 since 1993 but less than half was screened in 2012. At-risk individuals such as women, adolescents, and those entering juvenile detention centers are often missed due to the lack of awareness in healthcare providers and limited resources. Young women entering correctional services are at higher risk of chlamydia and high prevalence of chlamydia has been found. The CDC has recommended for the universal screening of females during intake in juvenile correctional services and screening rates increased from 55%-58% from 2005-2008. Therefore, the questions are how to promote chlamydia infection awareness; how to reach the target population; and what environment changes encourage screening.
While asymptomatic individuals are unlikely to obtain a routine check-up, clinicians also admitted to being hesitant in screening sexually active asymptomatic females. High-risk population should be linked to different health contacts such as pap smears, sexual health consultations or in pharmacy. Self-collection was found to significantly increase uptake and preferred over clinic-based testing in women aged 14-50 years. Self-collection strategies should be promoted to adolescents via social media because social media is a popular portal for teenagers to exchange and share information. Social media interventions have been shown to be effective in significantly increasing syphilis and HIV testing in youth and in promoting HIV testing in MSM. However, the effectiveness of social media interventions has not been demonstrated for chlamydia testing. This calls for further research in social media campaigns to increase chlamydia testing amongst adolescents. Another approach is to implement structural changes to alter the attitudes of healthcare providers in that they make testing adolescents a priority. Healthcare providers should also receive proper training so that they are able to approach adolescent patients confidently for chlamydia screening. Structural interventions mentioned previously did not focus on adolescents hence development of adolescent focused programs is needed.

In essence, we want to know whether screening interventions are able to reduce chlamydia’s disease burden. Some studies revealed that chlamydia screening reduced chlamydia infections and that screening women with a certain range of risk factors reduced PID incidence, other studies claim a lack of evidence in supporting opportunistic screening in the general population below 25 years of age. While our review identified a large amount of screening programs, many reviews did not include data such as treatment rate and the effect on chlamydia associated morbidity. As we relied on the analysis and data presented by primary authors, this exclusion is sub-optimal. The lack of evidence on the effectiveness of chlamydia screening programs in reducing disease burden has caused several countries to focus on case identification and management. A recent review has suggested a shift from an infection-based focus to increase screening uptake in asymptomatic populations, to a health outcomes-based focus to improve case detection among high-risk populations and case management. Greater emphasis need to be on strategies for infected individuals to minimize re-infection such as improving partner notification, treatment of sexual partners or re-testing.

Our methodology has a few limitations. First, it depended on the inclusion and analysis of primary studies by the review’s authors. Second, included reviews differed significantly in terms of intervention design, target populations, settings, and hence, a combination of different outcome measures. Paper heterogeneity has made comparison of effectiveness difficult at times. Apart from screening coverage and prevalence, other data regarding treatment, partner management, and retesting which is vital in determining its success, was often unavailable. Lastly, the results are presented without focus on the contextual nature of the studies. Factors such as cultural attitudes, government policies, and differences in healthcare system could have effects on the outcomes.

**Conclusion**
There is evidence that shows the most significant criterion in chlamydia screening was the adolescents’ age range such that national programs should focus on young males and females in the general population rather than individuals with high-risk characteristics. Reminders and outreach in certain community settings increased screening, but further information regarding cost-effectiveness is needed. Four interventions at the policy level were found to be effective; while the interventions differ, they share similar educational, advisory, and supervisory elements. Structural interventions are vital in changing the attitudes and awareness of chlamydia screening to result in systemic change. Therefore, initiatives to train healthcare providers in carrying out appropriate testing for adolescents is needed.
