ABSTRACT
The angular momentum of dark matter haloes controls their spin magnitude and orientation, which in turn influences the galaxies therein. However, the process by which dark matter haloes acquire angular momentum is not fully understood; in particular, it is unclear whether angular momentum growth is stochastic. To address this question, we extend the genetic modification technique to allow control over the angular momentum of any region in the initial conditions. Using this technique to produce a sequence of modified simulations, we can then investigate whether changes to the angular momentum of a specified region in the evolved universe can be accurately predicted from changes in the initial conditions alone. We find that the angular momentum in regions with modified initial conditions can be predicted between 2 and 4 times more accurately than expected from applying tidal torque theory. This result is masked when analysing the angular momentum of haloes, because particles in the outskirts of haloes dominate the angular momentum budget. We conclude that the angular momentum of Lagrangian patches is highly predictable from the initial conditions, with apparent chaotic behaviour being driven by stochastic changes to the arbitrary boundary defining the halo.

Key words: methods: numerical – galaxies: formation – galaxies: haloes – dark matter.

1 INTRODUCTION
A pressing question in galaxy formation theory is the origin of the angular momentum of dark matter haloes and of their host galaxies. Angular momentum controls the spin magnitude and orientation of dark matter haloes, which in turn influences the galaxies they host (Fall & Efstathiou 1980; Mo, Mao & White 1998; Bullock et al. 2001; Burkert et al. 2016). Beyond its relevance to galaxy formation, the origin of angular momentum also has consequences for cosmology. Due to its common cosmological origin, the angular momentum accreted by neighbouring galaxies tends to be aligned, which in turn contributes to the alignment of galaxy spins. This effect is degenerate with the lensing signal, and therefore needs to be mitigated to extract cosmological information from weak lensing surveys (e.g. Euclid, Laureijs et al. 2011; LSST, Ivezić et al. 2019).

The current understanding of the origin of the angular momentum of galaxies and dark matter haloes is built on the work of Doroshkevich (1970), who derived the first models to predict the evolution of angular momentum within non-spherical regions. The authors showed that angular momentum grows linearly under the Zel’dovich approximation (Zel’Dovich 1970), while its magnitude in spherical regions grows only at second order (Peebles 1969). The model was later improved by White (1984) to formulate ‘tidal torque theory’. The theory states that in the linear regime of structure formation, angular momentum is generated from slight misalignments of the inertia tensor of the Lagrangian patch with the tidal shear tensor.

As the proto-halo decouples from the expansion of the Universe and collapses, the coupling weakens and eventually vanishes. After decoupling, tidal torque theory assumes little evolution of the angular momentum. Later studies confirmed that tidal torque theory predictions are accurate within a factor of two if the angular momentum growth is stopped around turn-around (Sugerman, Summers & Kamionkowski 2000; Porciani, Dekel & Hoffman 2002a). Tidal torque theory provides a global explanation to the origin of angular momentum and successfully explains a variety of cosmological effects. It was, for example, recently extended by Codis, Pichon & Pogosyan (2015) to relate the structure of the tides imposed by the large-scale environment to the angular momentum acquisition of forming haloes, which provided a convincing explanation for the observed spin alignment signal (Tempel, Stoica & Saar 2013). Its predictions are, however, only accurate statistically and display significant deviations when looking at individual haloes (Porciani, Dekel & Hoffman 2002b).

A different picture emerges in studies which focus on dark matter haloes instead of Lagrangian patches. On average, the angular momentum of haloes grows with each merger (Vivitskaya et al. 2002; Peirani, Mohayae & de Freitas Pacheco 2004; Hetznecker & Burkert 2006). This motivated the development of semi-analytical models, where the angular momentum evolution is controlled by the haloes’ merger tree. In these models, each dark matter halo is initially seeded with a random angular momentum. After each merger, the angular momentum of the new halo is set by the angular momentum of its progenitors and their (randomly drawn) orbital parameters (Vivitskaya et al. 2002). Semi-analytical models were later refined using more accurate merger trees, halo concentrations, and

distributions of orbital parameters (Benson & Bower 2010). This allows accurate reproduction of the distribution of spin parameters measured in N-body simulations (Benson, Behrens & Lu 2020).

The two competing approaches seem to be in tension: according to tidal torque theory, the angular momentum of a given proto-halo can be derived from a linear analysis of its initial conditions. On the other hand, the angular momentum yielded by semi-analytical models is intrinsically stochastic, and depend on the initial conditions indirectly, through the merger history.

In this paper, we address the question of whether the actual angular momentum of given regions in the Universe results from chaotic processes, or whether it can be predicted accurately from an analysis of the initial conditions. To do so, we develop an extension to the genetic modification technique (Roth, Pontzen & Peiris 2016; Stopyra et al. 2020) to control the angular momentum of arbitrary regions in the initial conditions. The technique allows us to change the initial angular momentum through small modifications of the initial density field that minimally affect the large-scale environment.

Using a suite of simulations, we then investigate how the angular momentum in the evolved Universe changes with modifications of the initial conditions. We can thus test cause and effect relations between changes in the initial angular momentum and its late time evolution. This allows us to disentangle the effect of chaotic evolution from the effect of particle membership on angular momentum evolution. In Section 2, we describe our simulation setup. Our results are presented in Section 3, and we conclude in Section 4.

2 METHODS

All our simulations employ the code RAMSES (Teyssier 2002). We first perform a reference dark-matter-only cosmological N-body simulation. The adopted cosmology has a total matter density $\Omega_m = 0.31$, a dark energy density of $\Omega_{\Lambda} = 0.69$, a Hubble constant of $H_0 = 67.3 \, \text{km} \, \text{s}^{-1} \, \text{Mpc}^{-1}$, a variance at 8 Mpc $h^{-1} \, \sigma_8 = 0.8159$, and a non-linear power spectrum index of $n_s = 0.9667$, compatible with the parameters of Planck Collaboration XIII (2015). We start with a coarse grid of 256$^3$ (level 8) in a box of comoving size 50 Mpc $h^{-1}$ for a dark matter particle mass of $9 \times 10^8 M_\odot$. We use a quasi-Lagrangian refinement strategy: a cell is refined if it contains 8 or more dark matter particles. The gravitational potential is computed on the adaptive grid with a multigrid particle-mesh solver up to level 11 (Guillet & Teyssier 2011) and with the default conjugate gradient method for finer levels. We have an effective minimum softening length of physical size 0.8 kpc imposed by the grid resolution. We dump a snapshot every 250 My for a total of 55 outputs.

We extract a halo catalogue using ADAPTAHOP (Aubert, Pichon & Colombi 2004), with the ‘Most massive Sub-node Method’ and the parameters proposed by Tweed et al. (2009). Only haloes with 200 or more particles are kept. We verified that performing the same analysis with haloes containing more than 2000 particles yield similar results, although with smaller statistics.

We then select the first seven haloes from the halo catalogue that are more massive than $5 \times 10^{12} M_\odot$ ($3.5 \times 10^{12} M_\odot h^{-1}$, more than 5000 particles) at $z = 0$, and whose Lagrangian patch does not contain any particle within 0.1 $L_{box}$ of the box sides. The main properties of the selected haloes are presented in Table 1. Here, we used the following definition to compute the spin parameter: $\lambda = I \sqrt{K + U} / GM^{3/2}$, where $G$ is the gravitational constant and $I$, $K$, $U$, and $M$ are, respectively, the specific angular momentum, the kinetic energy, the potential energy, and the halo mass as computed by the halo finder.

For each halo, we trace back the region that contains all particles within the halo at $z = 0$ (their Lagrangian patch) to the initial conditions at $z = 99$. We then generate, for each region, a set of eight genetically modified initial conditions with a modified angular momentum: $\times 1/4, \times 1/2, \times 0.8, \times 0.9, \times 1.1, \times 1.2, \times 2$, and $\times 4$. We generate the initial conditions using the code GENETIC v1.2 (Roth et al. 2020) to control the angular momentum of arbitrary regions in the initial conditions. The technique allows us to change the initial angular momentum through small modifications of the initial density field that minimally affect the large-scale environment.
et al. 2016; Rey & Pontzen 2018; Stopera et al. 2020; Pontzen et al. 2021), that includes angular momentum genetic modifications; see Appendix A for the details of the implementation. This technique allows us to arbitrarily modify the total angular momentum within the patch by altering the initial density field. The genetic modification method ensures that these modifications are minimal and keep the large-scale environment as near unchanged as possible. This provides us with a numerical setup to quantify how changes in the initial angular momentum affect its growth rate and test whether the late-time evolution is chaotic or not. For each patch, we modify the three components of the initial angular momentum by the same relative amount, while keeping the mean density fixed. In the remainder of the paper, we will study the evolution of the angular momentum within these regions.

The result of the ×0.8 modification for the initial conditions of halo 386 can be seen in Fig. 1. We show in the top panel the mean density field and in the bottom panel the density modification required to alter the angular momentum. The figure shows that the modification extends significantly outside the Lagrangian region, and displays a distinct quadrupolar structure. This can be understood qualitatively by recalling that, under the Zel’dovich approximation, the angular momentum of a region originates from peculiar velocity gradients (as detailed in Appendix A and underlined by Neyrinck et al. 2020). Pontzen et al. (2020) showed that the density modifications corresponding to velocity modifications extend to scales of the order of 60 Mpc h⁻¹ in a ΛCDM universe. Since our simulations have a comoving size of 50 Mpc h⁻¹, we therefore expect the density modification to extend to the entire simulation domain.

We perform resimulations starting from each of the modified initial conditions (7 × 8 in total) with the same parameters as in the reference simulation. For all resimulations, we compute the angular momentum of the region that was modified, and obtain its specific angular momentum by dividing by the mass it contains (see Table 1).

3 RESULTS

Tidal torque theory provides a prediction for the time evolution of the specific angular momentum in a region,

$$l_{\text{pred}}(z) = l_0 \times \left( \frac{a(z)D(z)}{a_0^2 D_0} \right),$$

(1)

where $l_0$ is the initial specific angular momentum within the region, $a$ is the expansion factor, $D$ is the linear matter growth function, and $a_0$ and $D_0$ are their respective initial value. Here, dots indicate time derivatives. However, when performing modified simulations, we do not need to rely directly on tidal torque theory. Instead, we can use the measured value of the specific angular momentum in the reference simulation to estimate the growth rate,

$$l_{\text{pred}}(z) = l_0 \times \frac{l_{\text{meas}}(z)}{l_{\text{pred},0}},$$

(2)

where $l_{\text{meas}}(z)$ is the measured magnitude of the specific angular momentum in the reference simulation and $l_{\text{pred},0}$ is its value in the initial conditions.

In our suite of resimulations, the ratio of the initial specific angular momentum $s$, $ls_{\text{ref}},0$, is equal to the amplitude of the specific angular momentum modification. Using measurements of $l_{\text{ref}}(z)$ and the $7 \times 8$ modified resimulations with known $ls_{\text{ref}},0$, we can compare the accuracy of the ansatz (2) to the accuracy of tidal torque theory. To do so, we show in Fig. 2 the deviation from unity of the ratio of our prediction to the measured value, $l_{\text{pred}}/l_{\text{meas}} = 1$ (as coloured lines, for different amplitudes of the modifications) for the eight resimulations of the seven haloes. If the specific angular momentum in the resimulations is proportional to its value in the reference simulation, we will study the evolution of the angular momentum affect its growth rate and test whether the late-time evolution is chaotic or not. For each patch, we modify the three components of the initial angular momentum by the same relative amount, while keeping the mean density fixed. In the remainder of the paper, we will study the evolution of the angular momentum within these regions.

The result of the ×0.8 modification for the initial conditions of halo 386 can be seen in Fig. 1. We show in the top panel the mean density field and in the bottom panel the density modification required to alter the angular momentum. The figure shows that the modification extends significantly outside the Lagrangian region, and displays a distinct quadrupolar structure. This can be understood qualitatively by recalling that, under the Zel’dovich approximation, the angular momentum of a region originates from peculiar velocity gradients (as detailed in Appendix A and underlined by Neyrinck et al. 2020). Pontzen et al. (2020) showed that the density modifications corresponding to velocity modifications extend to scales of the order of 60 Mpc h⁻¹ in a ΛCDM universe. Since our simulations have a comoving size of 50 Mpc h⁻¹, we therefore expect the density modification to extend to the entire simulation domain.

2We expect angular momentum modifications to translate into quadrupolar density modifications. Pontzen et al. (2020) showed that velocity modifications translate into dipolar modifications of the density field, so that the modification of the gradient of the peculiar velocity required to modify the angular momentum translates into a quadrupolar density modification.
simulation, the ratio will be equal to one. In order to qualitatively compare any deviations from one to the accuracy of tidal torque theory, we measure the relative 68 per cent confidence interval of tidal torque theory’s predictions compared to the measured values,\(^3\) using all 700 haloes more massive than \(12 \times 10^7\) in the reference simulation (grey bands).

Both tidal torque theory and our ansatz (2) are accurate in the early, linear Universe. With increasing cosmic time, we observe that the accuracy of tidal torque theory worsens, as shown by the widening of the 68 per cent interval which, at \(z = 0\), has a width of \(\pm 0.6\). The deviations of our ansatz from the measured value are statistically within the contours set by tidal torque theory down to \(z = 0\), indicating that the ansatz (2) is more accurate than tidal torque theory. We also note that large deviations are only ever obtained from large modifications of the initial specific angular momentum (such as halo 123 × 1/4 and halo 189 × 4).

Let us now study in more detail the evolution of the deviation of our predictions from the actual value with cosmic time. We show in Fig. 3 the evolution of the median (solid lines) and 68 per cent confidence interval (shaded regions) of \(l_{\text{pred}}/l_{\text{meas}} - 1\). We compute the median and confidence interval of the ratio from three different subsets of resimulations: all of them (0.25 \(\leq l_0/l_{\text{rel},0} \leq 4\); orange line), all but most extreme modifications (0.5 \(\leq l_0/l_{\text{rel},0} \leq 2\); blue line and blue shaded area), and only those with small specific angular momentum modifications (0.8 \(\leq l_0/l_{\text{rel},0} \leq 1.2\); bluish green line). We show the confidence interval for one subset of resimulations for the sake of clarity, the two others being presented in Fig. 4. We also show the median and 68 per cent interval we obtain with tidal torque theory (in grey).

The predictions made with ansatz (2) slightly underestimate the actual angular momentum, as shown in Fig. 3 by a weak deviation of the median from unity (of the order of 0.9–0.95) at \(z \approx 1\). The

\(^3\)We define the relative confidence interval as the measure of the deviations around the median value, and is given by the ratio of the 68 per cent confidence interval to the median of \(l_{\text{pred}, \text{TTT}}/l_{\text{meas}} - 1\). This allows us to correct for the fact that, by \(z = 0\), the predictions are systematically \(\sim 3\) larger than the actual value.

Figure 3. Evolution of the deviation of the predicted angular momentum from the measured value. Predictions rely either on tidal torque theory (grey line) or on the reference simulation (from green to blue to orange in increasing order of the amplitude of modifications, as labelled). The shaded regions indicate 68 per cent confidence intervals. Tidal torque theory systematically overpredicts the measured specific angular momentum, and its predictions are significantly more scattered than predictions based on a reference simulation. The latter are consistent with unity: they are less biased and more accurate, especially at low redshift.

Figure 4. Time evolution of the 68 per cent confidence interval of the ratio \(l_{\text{pred}}/l_{\text{meas}} - 1\), with the same colours as Fig. 3. At all times, predictions based on the reference simulation are less scattered around the true value than predictions from tidal torque theory. Smaller modifications of the initial specific angular momentum are progressively more accurate.

68 per cent confidence interval however remains consistent with unity at all times. Predictions from tidal torque theory are also consistent with the measured angular momentum at early times \(z \gtrapprox 1–2\), while at later times, we recover the well-established result that angular momentum growth stalls, and as a result tidal torque theory starts overpredicting the actual angular momentum. By \(z = 0\), tidal torque theory overpredicts the angular momentum by a factor as large as 3, in agreement with previous findings (Porciani et al. 2002a).

We conclude that the predictions from ansatz (2) are less biased than those from tidal torque theory, and remain consistent with the measured angular momentum down to \(z = 0\). We have also checked that similar conclusions can be made about the orientation of the angular momentum vector: ansatz (2) provides a more accurate prediction of the angular momentum orientation than tidal torque theory.

In order to compare the relative accuracy of tidal torque theory predictions to those of ansatz (2), we show the evolution of the relative 68 per cent confidence intervals of \(l_{\text{pred}}/l_{\text{meas}} - 1\) in Fig. 4. We recover here the result that, at \(z = 0\), predictions from tidal torque theory are only accurate within a factor of \(\sim 2\) (fluctuations of the order of 120 per cent). By contrast, we observe that the predictions of ansatz (2) are accurate within \(\sim 0.5\) of the measured angular momentum (for the largest modifications, \(l_0/l_{\text{rel},0} \in [0.25, 4]\) and within \(\sim 0.3\) (for the smallest modifications, \(l_0/l_{\text{rel},0} \in [0.8, 1.2]\)) at \(z = 0\). We also observe that predictions based on our ansatz remain accurate down to a later time compared to predictions from tidal torque theory. For example, the relative confidence interval reaches half its final value as early as \(z \approx 2\) for tidal torque theory, compared to \(z \approx 1\) with our ansatz.

4 DISCUSSION

Our results demonstrate that the angular momentum of Lagrangian patches can be accurately predicted from the initial conditions, and allow us to rule out scenarios where it would be driven by chaotic or stochastic processes. Using the ansatz (2) we have shown that, for individual Lagrangian patches, the angular momentum can be predicted from the product of its initial value and a growth rate. We found the accuracy of our predictions at \(z = 0\) to be between 2 and 4 times better than the accuracy of tidal torque theory, with smaller modifications leading to more accurate predictions.

Given our findings, we argue that the problem of the origin of the angular momentum of dark matter haloes can be decomposed into...
two parts. The first issue is that of the origin of angular momentum growth, which we addressed in this work. Our results show that the growth rate of individual regions in resimulations can be estimated accurately from its measured value in a reference simulation. We interpret this as evidence that the growth rate is an intrinsic property of a given region and its environment, and that angular momentum does not result from chaotic processes. One implication for tidal torque theory is that its accuracy could be improved by predicting (rather than measuring) this growth rate from an analysis of the Lagrangian patch in the linear Universe.

The second aspect is the problem of the initial value of the angular momentum in the linear Universe, i.e. the term $l_0$ in equations (1) and (2). As was already pointed out by White (1984), Porciani et al. (2002b), we would need a robust method to draw the boundaries of the Lagrangian patch to solve this problem. For dark matter haloes, these two aspects are not independent because the tidal field, which controls the torquing, and the inertia tensor, which controls the shape of the Lagrangian patch, are correlated. This remains a topic for future research, and currently limits the possibility of using genetic modifications to control the angular momentum of haloes rather than fixed regions as modifications by construction deform the Lagrangian patch.

However, we argue that it should be possible to control the angular momentum of simulated galaxies. The distribution of the angular momentum of the gas is much more concentrated, and more coherent radially than the dark matter angular momentum (Danovich et al. 2015). We therefore expect the gas angular momentum to be less sensitive to deformation of its Lagrangian patch. In particular, galaxies that are fed through cold flows are good candidates for testing this hypothesis. The flows are aligned with the cosmic web which sets their angular momentum and direction (Danovich et al. 2012; Pichon et al. 2014), and they feed most of the baryonic angular momentum to the galaxies (Birnboim & Dekel 2003; Stewart et al. 2017). We expect the structure of the cosmic web to be only marginally impacted by genetic modifications (Stopyra et al. 2020), giving us a potential lever for controlling the angular momentum in the flows, and hence in the infalling gas. In the future, we will apply genetic modifications to study the origin of angular momentum in galaxies, and how different angular momentum acquisition histories lead to different galactic properties, such as their morphology or disc structure.

**ACKNOWLEDGEMENTS**

The authors acknowledge Nina Roth’s unpublished preliminary work on genetic modifications of angular momentum, which motivated this project. We would like to thank R. Teyssier and the anonymous referee for useful comments. **APPENDIX A: GENETIC MODIFICATIONS OF THE ANGULAR MOMENTUM**

We provide in this section a qualitative description of the implementation of angular momentum genetic modifications. We refer to Roth.
Predicting angular momentum evolution

et al. (2016), Rey & Pontzen (2018), Stopyra et al. (2020) for a more formal derivation of the genetic modification method.

Let us suppose we have initial conditions with values on a regular grid \( f^0 \), where \( i \) is the index of each cell, drawn from a Gaussian random field with covariance matrix \( C \).

We can represent any linear function of the field as \( \mathbf{u} \cdot f = d \). Modifications of the initial conditions can be found by updating \( f \) to \( f' \) to satisfy the requirement

\[
\mathbf{u} \cdot f' = d',
\]

where \( f' \) has the same power spectrum as \( f \) and \( d' \) is an arbitrary value. In general, equation (A1) does not admit a unique solution. The genetic modification technique ensures unicity by further requiring \( f' \) to minimize the \( \chi^2 \) distance to the original field, i.e. to minimize \( (f' - f)^2 C^{-1} (f' - f) \). Note that \( f \) may be the density field \( \delta \) or the potential field \( \phi \).

In order to generate the initial conditions of the resimulations presented in Section 2, we implemented angular momentum modifications in GENETIC. Given equation (A1), this requires computing the three vectors \( \mathbf{u} \), where \( (i\delta \mathbf{f}) = (i\delta f_i) \), and \( (i\phi) = (i\phi) \) is the component of the specific angular momentum in the initial conditions. For a given Lagrangian patch \( \Gamma \), we can compute the specific angular momentum in the initial conditions using linear theory, as detailed in Section A.

Equation (B10) shows in particular that the initial specific angular momentum can be computed from the reduced potential field \( \phi \).

To do so, our algorithm first computes the reduced potential \( \phi \) on a regular grid, from the overdensity \( \delta \). We achieve this by solving the Poisson equation in Fourier space. Without loss of generality, let us focus on the particular case of the angular momentum in the \( z \) direction. Its value on a regular grid can be derived from equation (B10) as

\[
l_{z,0} \propto \sum_i \left[ (q_i^z - \bar{q}_z) \nabla_i \phi^{(i)} - (q_i^z - \bar{q}_z) \nabla_i \phi^{(i)} \right],
\]

where \( i \) runs over all the cells in \( \Gamma \), \( \bar{q} \) is the centre of mass, and we obtain the value of \( \nabla_i \phi^{(i)} \) using a fourth-order finite difference method. Then we find the linear operator \( \mathbf{u} \), such that \( \mathbf{u} \cdot \phi = l_{z,0} \),

where \( \phi \) is a vector containing the values of the potential in all cells of \( \Gamma \). To do so, we loop over all cells in \( \Gamma \) and update the value of \( \mathbf{u} \) as illustrated on Fig. A1. Once computed, the value of \( \mathbf{u} \) can readily be used to modify the angular momentum using the code GENETIC.

We have used this algorithm to generate the initial conditions in our suite of resimulations presented in Section 2.

### APPENDIX B: DETAILS OF TIDAL TORQUE THEORY

In Section 3, we compared the prediction from tidal torque theory, equation (1), to those relying on resimulations with modified initial conditions, equation (2). For the sake of completeness, we provide here a short derivation of tidal torque theory, following broadly the lines of White (1984). To do so, let us first consider a Eulerian patch \( \gamma \). Its angular momentum about the centre of mass, located at comoving position \( \bar{x} \) reads

\[
L = a^5 \int d^3 \mathbf{x} \rho(x - \bar{x}) \times \mathbf{v},
\]

where \( x \) is the comoving position, \( \mathbf{v} \) is the peculiar velocity, \( a \) is the expansion factor, and \( \rho \) is the density. Using the fact that \( a^3 \rho = a_0^3 \rho_0 (1 + \delta) \), with \( \delta \) the overdensity, \( a_0 \) the initial expansion factor, and \( \rho_0 \) the initial expansion density, we can express the angular momentum as

\[
L = a^2 a_0^3 \int d^3 \mathbf{x} (1 + \delta)(x - \bar{x}) \times \mathbf{v}.
\]

We can relate the comoving Eulerian position and velocity of a particle to its initial Lagrangian position plus a displacement,

\[
x(q, t) = q + S(q, t), \quad \mathbf{v}(q, t) = \frac{\partial S(q, t)}{\partial t}.
\]

When the displacement is small, the mapping is reversible and the flow is laminar. Under this assumption, we can write the mass conservation equation as

\[
d^3 x (1 + \delta) = d^3 q,
\]

so that equation (B2) becomes

\[
L = a^2 a_0^3 \int d^3 \mathbf{x} (\mathbf{x} - \bar{q}) \times \mathbf{v},
\]

where \( \Gamma \) is the Lagrangian region corresponding to the Eulerian region \( \gamma \). Note that this equation is exact in the laminar regime.

We can further simplify equation (B5) using the Zel'dovich approximation (Zel'dovich 1970). In particular, we will assume that the proportionality factor between the velocity potential and the gravitational potential \( \phi(q, t) \), which holds in the linear regime for the growing mode of density fluctuations \( \delta \propto D(t) \), can be extended into the mildly non-linear regime. This allows us to write in the mildly non-linear regime

\[
S(q, t) = -D(t)V \nabla \phi(q),
\]

where \( \phi \) is the solution to the (reduced) Poisson equation \( \nabla^2 \phi = \delta \). Plugging equation (B6) into equation (B5), finally obtain an expression for the angular momentum

\[
L = -a^2 D a_0^3 \int d^3 q (\mathbf{q} - \bar{q}) \times \nabla \phi.
\]

where \( D \equiv \partial D/\partial t \). We can obtain the specific angular momentum \( \mathbf{L} \) by dividing equation (B7) by the mass \( \rho_0 a_0^3 V \) enclosed in the region
with Lagrangian volume \( V_\Gamma = \int_{\Gamma} d^3q \), to obtain

\[
I(t) = -\frac{a^2 D}{V_\Gamma} \int_{\Gamma} d^3q (q - \bar{q}) \times \nabla \phi. 
\]  
(B8)

We can split this into a time-dependent part and a space-dependent part as

\[
I(t) = I_0 f_{\text{TTT}}(t). 
\]  
(B9)

The initial value of the specific angular momentum \( I_0 \) is given by

\[
I_0 \equiv -\frac{a_0^2 D_0}{V_\Gamma} \int_{\Gamma} d^3q (q - \bar{q}) \times \nabla \phi, 
\]  
(B10)

and the angular momentum growth rate is given by

\[
f_{\text{TTT}}(t) \equiv \frac{a(t)^2 D(t)}{a_0^2 D_0}. 
\]  
(B11)

Note that White (1984) suggested to further simplify equation (B10) using a Taylor development of the potential about the centre of the patch. This allows us to express the initial specific angular momentum in terms of the density and potential fields only, independently of \( \Gamma \), but at the cost of a decreased accuracy. In this paper, we compared predictions of the angular momentum with known initial values, and therefore did not follow this route. The expression of equation (B10) resembles the ‘spin from primordial inner motions’ concept (Neyrinck et al. 2020). In this formulation, the initial angular momentum is expressed as a function of the potential gradient, or equivalently of the peculiar velocity field in the Zeldovich approximation.

In Section 2, tidal torque theory’s prediction (equation 1) was derived by taking the norm of both sides of equation (B9). The form of the latter equation also suggests ansatz (2), where we replaced \( f_{\text{TTT}} \) with the measured growth rate in simulations, \( I_{\text{ref}}(z)/I_{\text{ref},0} \).
