Abstract

INTRODUCTION: As the number of biomarkers used to study AD continues to increase, it is important to understand the utility of any given biomarker, as well as what additional information a biomarker provides when compared to others.

METHODS: We used hierarchical clustering to group 19 cross-sectional biomarkers in autosomal dominant Alzheimer disease. Feature selection identified biomarkers that were the strongest predictors of mutation status and estimated years from symptom onset (EYO). Biomarkers identified included clinical assessments, neuroimaging, cerebrospinal fluid amyloid and tau, and emerging biomarkers of neuronal integrity and inflammation.

RESULTS: Three primary clusters were identified: neurodegeneration, amyloid/tau, and emerging biomarkers. Feature selection identified amyloid and tau measures as the primary predictors of mutation status and EYO. Emerging biomarkers of neuronal integrity and inflammation were relatively weak predictors.

DISCUSSION: These results provide novel insight into our understanding of the relationships among biomarkers and the staging of biomarkers based on disease progression.

Keywords: Autosomal dominant Alzheimer disease; Machine learning; Biomarkers

1 Introduction

Alzheimer disease (AD) is defined pathologically by the accumulation of amyloid beta plaques, neurofibrillary tangles (NFT), neuroinflammation, and neuronal/synaptic loss that leads to brain atrophy and decreased glucose metabolism [1]. These changes manifest clinically with cognitive decline and functional impairment. Autosomal dominant Alzheimer disease (ADAD) accounts for less than 1% of all AD cases and is caused by pathogenic mutations in amyloid precursor protein (*APP*), presenilin 1 (*PSEN1*), or presenilin 2 (*PSEN2*) that lead to early increases in amyloid Beta ($A\beta$) deposition in the brain [2,3]. The mean age of onset of cognitive impairment in ADAD mutation carriers (MC) is earlier than sporadic AD and remains consistent within a family, allowing for calculation of the estimated number of years from symptom onset (EYO) [4,5].

Multiple neuroimaging methods have been used to evaluate *in vivo* changes in the brain due to ADAD. [^{11}C]Pittsburgh Compound-B (PiB) has high affinity for $A\beta$ plaques, with distributions similar to those seen at autopsy [6]. In ADAD, PiB PET has identified $A\beta$ deposition occurring more than 20 years prior to estimated age of symptom onset in MC [5,7–9]. [^{18}F]Fluorodeoxyglucose (FDG) uptake reflects glucose metabolism and has shown the ability to discriminate symptomatic MCs from non-carriers (NC) [6,8,9]. Decreases in

1 glucose metabolism occur approximately 5–10 years before symptom onset in MCs [9,10].
2 Finally, structural MRI provides a method to evaluate volumetric and cortical thickness
3 changes associated with disease progression [11,12]. ADAD is characterized by progressive
4 atrophy that affects temporal and subcortical regions approximately 5 years from estimated age
5 of symptom onset [9].

11 Apart from neuroimaging, changes in cerebrospinal fluid (CSF) A β and tau biomarkers have
12 been identified. CSF markers of A β , including A β 42 and CSF A β 42/40 ratio, decrease during
13 the early stages of the disease and correlate with amyloid deposition in the brain [13,14]. Tau
14 is an abundant microtubule-associated protein that is regulated by phosphorylation. Tau that is
15 in a hyperphosphorylated state can form aggregates that lead to NFTs. Levels of CSF total tau
16 are elevated in MCs approximately 10 years from estimated age of symptom onset [15]. More
17 recently, mass spectrometry studies showed that phosphorylated/unphosphorylated ratios of
18 tau isoforms are associated with specific stages of the disease [16].

33 Additional CSF and plasma biomarkers, generally referred to as “emerging” biomarkers, have
34 recently been studied in AD. Neurogranin is a postsynaptic protein expressed in dendritic
35 spines, and correlates with elevated levels of tau [17]. Synaptosomal-associated protein-25
36 (SNAP-25) is involved in the fusion of synaptic vesicles to the pre-synaptic membrane.
37 Increases in CSF neurogranin and SNAP-25 are thought to reflect synaptic damage [18].
38 Visinin-like protein 1 (VILIP-1) is a calcium sensor protein and is also a marker of neuronal
39 injury [18]. Chitinase-3-like protein 1 (YKL-40) is a secreted glycoprotein primarily expressed
40 by astrocytes and has been associated with neuroinflammation [19,20]. Finally, neurofilament
41 light chain (NfL) is found within axonal cytoskeleton and is elevated in symptomatic AD
42 [21,22].

While the number of biomarkers used to study AD continues to increase, the utility of a given measure in providing additional information when compared to other biomarkers remains unclear. Data driven methods capable of identifying which biomarkers are most reflective of AD progression and staging would be beneficial to clinical trials and patient care. Machine learning (ML) is a method for generating models that learn from existing data rather than being constrained by *a priori* rules [23]. ML methods do not rely on heuristics, are robust to feature interactions, and are sensitive to complex association patterns. The ability to identify MCs and accurately determine an individual's position relative to symptomatic impairment provides a unique opportunity for ML to evaluate similarities among biomarkers and identify which biomarkers are most reflective of mutation status and EYO.

The goal of this study was to identify natural groupings of biomarkers based on disease progression, as well as identify what biomarkers are most reflective of disease status and EYO within a cross-sectional cohort of MCs (n=130) and NCs (n=79). We used hierarchical clustering to group biomarkers based on similarity, and decision tree-based feature selection to identify biomarkers that were the strongest predictors of mutation status and EYO. This data-driven approach provide insight into both the behavior and utility of existing biomarkers for ADAD and could be important for clinical trials evaluating therapies. Further, these results could provide a better understanding of other forms of AD.

2. Methods

2.1 Participants

MCs (n=130) with pathogenic mutations in *PSEN1*, *PSEN2*, or *APP* and healthy, mutation-negative sibling NCs (n=79) were recruited from sites participating in the Dominantly Inherited Alzheimer Network (DIAN). Participants from the 14th data freeze with genetic, clinical, and

neuroimaging data who passed quality control procedures and had a complete set of biomarkers were included. A single time point from each participant was used for analysis. The Washington University in Saint Louis (WUSTL) Institutional Review Board provided supervisory review and human subject approval. Participants provided written, informed consent or assent with proxy consent. All study procedures were approved by the WUSTL Human Research Protection Office and the institutional review boards of the participating sites.

2.2 Clinical Classification

The clinical dementia rating (CDR)[®] Dementia Staging Instrument, which includes its sum of boxes (CDR-SB), and the Folstein Mini-Mental State Examination (MMSE) were performed at each clinical assessment [24,25]. Depression was measured using the Geriatric Depression Scale (GDS) [26]. A participant's EYO was calculated based on the participant's current age relative to the family mutation-specific expected age at onset of dementia symptoms [4]. Parental age at first progressive cognitive decline was used if the mutation-specific age of onset was unknown. EYO was calculated identically for both MCs and NCs. In the context of NCs, increasing EYO essentially serves as a proxy measure for increased aging. Mutation status was determined using polymerase chain reaction amplification followed by Sanger sequencing [5].

2.3 MRI Acquisition and Processing

MRI was performed using the Alzheimer's Disease Neuroimaging Initiative (ADNI) protocol [27]. Sites used a 3T scanner that passed quality control assessments. The ADNI Imaging Core screened images for compliance. T1 weighted images at 1.1 x 1.1 x 1.2 mm voxel resolution were acquired for participants. FreeSurfer 5.3 [28,29] was used to perform volumetric segmentation, cortical surface reconstruction, and to define cortical and subcortical regions of interest (ROIs). A regression approach was used to correct subcortical volumes for intracranial

volumes. FreeSurfer-defined ROIs were used for regional processing of PET data. Cortical signature (CorSig) was calculated for subsequent analyses [30].

2.4 PET Acquisition and Processing

Amyloid PET was performed using a bolus injection of 8-18 mCi PiB. Data from the 40–70 minute post-injection timeframe were converted to regional standardized uptake value ratios (SUVRs) relative to the cerebellar gray matter [31]. PET glucose metabolism imaging was performed with a single bolus injection of 5 mCi fluorodeoxyglucose (FDG). A 30-minute dynamic acquisition beginning 30 minutes post-injection was acquired. The last 20 minutes of each FDG scan were converted to SUVRs using the cerebellar gray matter as a reference region. All PET data were partial volume corrected and aligned to the T1 image [32,33]. Scanner-specific filters were applied to achieve a common resolution (8 mm) [34]. A summary measure representing the arithmetic mean of SUVRs from the precuneus, superior and rostral middle frontal, lateral and medial orbitofrontal, and superior and middle temporal was used for PET analyses [31].

2.5 CSF Acquisition and Processing

CSF was collected using methods previously described [13]. Ten to twenty mL of CSF were collected during a fasting state via standard lumbar puncture (LP) at 08:00 hours under gravity flow. Samples were collected, flash frozen on dry ice, and shipped to the DIAN Biomarker Core at WUSTL, at which point they were thawed on wet ice, aliquoted (0.5 mL), flash frozen, and stored at -80°C. Concentrations of CSF A β 40, A β 42, total tau, and total p-tau (181) were measured by chemiluminescent enzyme immunoassay using an automated platform (LUMIPULSE G1200, Fujirebio) according to manufacturer's specifications. CSF Neurogranin, SNAP-25, and VILIP-1 were measured with microparticle-based immunoassays

1 using Single Molecule Counting technology [17,35,36]. CSF YKL-40 (Quidel) was measured
2 via commercial ELISAs according to manufacturer recommendations. CSF p-tau extracts were
3 analyzed by nanoLC-MS/HRMS using Parallel Reaction Monitoring using HCD
4 fragmentation. NanoLC-MS/MS experiments were performed using a nanoAcquity UPLC
5 system (Waters) coupled to a Fusion Tribrid mass spectrometer (Thermo Scientific). CSF tau
6 phosphorylation levels were calculated using ratios between MS/HRMS transitions of
7 endogenous unphosphorylated peptides and ¹⁵N labeled peptides from protein internal
8 standard. Ratios of phosphorylation on T181, S202, T205 and T217 were measured using the
9 ratio of the MS/HRMS transitions from phosphorylated peptides and corresponding
10 unphosphorylated peptides (pT217/T217, pT205/T205, pT181/T181) [16].

26 **2.6 Blood Acquisition and Processing**

27
28
29 Serum NfL was acquired and processed using methods previously described [22]. In short,
30 blood was collected in the morning under fasting conditions by venipuncture using red top
31 plain Vacutainer tubes (Becton, Dickinson and Company). Tubes were centrifuged at 2,000g
32 at room temperature for 15 minutes after clotting. Serum was taken into a single transfer tube
33 (SARSTEDT AG & Co.) and frozen on dry ice. Measurements were performed using a single-
34 molecule array assay using the capture monoclonal antibody 47:3 and the biotinylated detection
35 antibody 2:1 (UmanDiagnostics AB) [37]. The samples were measured in duplicate on a Simoa
36 HD-1 platform (Quanterix) using a two-step neat assay. Serum samples were measured at 1:4
37 dilution (Tris-buffered saline, 0.1% Tween 20, 1% non-fat milk powder, HeteroBlock
38 [300 ug ml⁻¹; Omega Biologicals]). The median number of days between biomarker
39 collections (imaging, CSF, plasma) per visit was 1 day ± 12.4 days.

2.7 Machine Learning and Statistical Analyses

Analyses were performed in MATLAB R2021a. All measures were standardized to zero mean and unit variance. Predictive features of mutation status and EYO were ranked according to importance using decision tree-based feature selection [38]. This method utilizes a curvature test that identifies the strongest predictors by minimizing the p -value of chi-square tests of independence between each predictor and the response, as well as each pair of predictors and response. When evaluating the strongest features of mutation status, classes were weighted such that each class accounted for 50% of the accuracy. All decision trees were validated with 10-fold cross validation. Clustering was performed with agglomerative hierarchical clustering. We chose hierarchical clustering because 1) ease of interpretability of results, 2) the hierarchical nature of the algorithm does not require a predetermined number of clusters, and 3) the results can be viewed at different scales based on the needs of a given study. Agglomerative hierarchical clustering is a bottom-up approach, where each observation starts in its own cluster, and clusters are merged as they move up the cluster tree. The distance metric utilized was the absolute value of the biomarker correlations. The linkage criterion, which determines the distance between sets as a function of the pairwise correlations between biomarkers, used Weighted Pair Group Method with Arithmetic Mean [39]. Supplemental material provides further details on the cluster analysis.

3. Results

3.1 Demographics

Detailed demographics are presented in Table 1. NC and MC participants were similar with regards to age, sex, race, and education.

3.2 Clustering

The clustering results can be seen in Figure 1, and the similarity matrix used for clustering in Supplementary Figure 1. At the highest level, the data were grouped into three categories: neurodegeneration, A β /tau, and emerging biomarkers of neuronal integrity and inflammation. The A β /tau cluster consisted of all CSF tau-related variables, PiB, and CSF A β 42 and A β 42/40 ratio. Within the amyloid/tau cluster, PiB showed greater similarity with CSF tau variables compared to A β variables. The neurodegeneration cluster consisted of clinical (CDR-SB), neuropsychological (MMSE), and measures of neuronal dysfunction/damage (FDG, cortical signature, and serum NfL). Lastly, except for CSF A β 40, the emerging biomarkers of neuronal integrity and inflammation clustered together and consisted of CSF neurogranin, SNAP-25, VILIP-1, and YKL-40. GDS was the least similar to any other biomarker. Supplemental material and Supplementary Figure 6 provide further details on cluster validation results.

3.3 Mutation Status Feature Selection

The decision tree was able to classify mutation status with an average accuracy of 92.4%. Figure 2 shows the strongest predictors of mutation status by EYO calculated over a 15-year sliding window. The strongest predictors were markers of A β and mass spectrometry tau ratios (CSF A β 42/40, PiB, and CSF pTau 217, pT181). CSF A β 42/40 and PiB showed an inverse trajectory, with A β 42/40 being the strongest predictor during the early phase of the disease (EYO < -15) and decreasing in predictive strength later in the disease process (EYO > 0), while PiB showed the opposite pattern and was a stronger predictor at later EYO. The CDR-SB was the strongest clinical predictor of progression but not until EYO \geq 0. The emerging biomarkers of neuronal integrity and inflammation, FDG, and cortical signature were not identified as strong predictors.

3.4 EYO Feature Selection

The utility of each biomarker for predicting EYO is shown in Figure 3 for MC (red) and NC (blue). The decision tree was able to predict EYO with a mean squared error of 6.4 years. Feature selection identified phosphorylated tau measures (pT205, pT217, pT181 ratios) as the strongest predictors of EYO. Interestingly, YKL40, ptau181 measured with immunoassay, and serum NfL were strong predictors for both MCs and NCs. Within NC, YKL40, serum NfL, and ptau181 by immunoassay were the strongest predictors, indicating a potential aging component regardless of disease pathology (Figure 4 and supplementary Figure 4). When accounting for age, the strongest predictors of EYO were CSF pT217, pT205, and pT181 ratios by mass spectrometry, as well as CDR-SB.

4. Discussion

We used hierarchical clustering to identify groupings of biomarkers reflective of ADAD pathology. Neurodegeneration, amyloid/tau, and emerging biomarkers of neuronal integrity and inflammation were the three primary clusters. Decision tree-based feature selection recognized measures of A β and tau as the primary predictors of mutation status throughout disease progression, while neurodegenerative and clinical measures were moderate predictors in the later stages of the disease ($EYO \geq 0$). The emerging biomarkers of neuronal integrity and inflammation were not identified as strong predictors. When evaluating time from symptom onset, CSF phosphorylated tau measures and clinical metrics were the strongest predictors for MCs. Finally, serum NfL and CSF YKL40 were strong predictors of aging regardless of mutation status.

Clustering revealed three primary groupings for biomarkers. The amyloid/tau cluster encompassed all CSF and PET measures except for CSF A β 40. Because A β 40 did not start to

deviate for MCs compared to NCs until -10 to -5 EYO (supplementary Figure 5), it was likely grouped into a different cluster because other amyloid and tau measures showed differences at earlier stages of the disease. CSF A β 42 and CSF A β 42/40 ratio grouped together, while phosphorylated tau measures also grouped together. This indicates that while specific phosphorylation sites may be more correlated with measures of amyloid or tau, the overall progression is similar for each of the tau phosphorylation measures. PiB's position in the dendrogram indicated it was more like CSF tau than A β . PiB also showed a higher correlation (absolute value) with tau measures (A β 42=.49, A β 42/40=.54, pT181=.54, pT205=.67, pT217=.66, all $p < .001$). This is likely due to the plateau that occurs in A β 42/40 around EYO=0 which does not occur in PiB and CSF tau species (Figure 4 and 5).

The neurodegeneration cluster consisted of clinical and psychological measures (CDR-SB and MMSE), neuroimaging measures of neurodegeneration (CortSig and FDG), and serum NfL. Consistent with the amyloid-tau-neurodegeneration (AT(N)) framework [40], differences in neurodegenerative measures between MCs and NCs deviated at roughly -5 EYO (Figure 4 and supplementary Figure 5). Serum NfL showed the earliest changes and was highly correlated with CDR-SB and MMSE (.67 and .62, $p < .001$). All biomarkers in the neurodegeneration cluster were highly correlated ($>.5$) with CSF pT205, which is consistent with previous findings [16].

The last cluster consisted primarily of the emerging biomarkers of neuronal integrity and inflammation. The trajectories for these biomarkers can be seen in Supplementary Figure 4. Among these measures, SNAP 25 and neurogranin, both presumed to be measures of synaptic damage, showed the greatest consistent ability to distinguish between MCs and NCs (Figure 2). SNAP25 showed a slight elevation in MCs that remained relatively consistent regardless of EYO. VILIP, SNAP25, and YKL40 all showed increases with age regardless of mutation

status. This suggest many of these biomarkers are more likely measures of aging and not specific to AD.

Both Figure 2 and Supplementary Figure 2 illustrates CSF A β 42/40 and PiB were the strongest predictors of mutation status. This could be explained by a dramatic increase in amyloid deposition within MC brains around 15 years before EYO; alternatively, it could be explained by more MCs beginning to accumulate amyloid plaques during this phase of the disease. CSF A β 42/40 was the strongest predictor earlier in the disease process but lost predictive strength in later stages. This result agrees with a previous study [5] that has shown changes in CSF A β 42 occur early in the disease and begin to plateau as they approach EYO=0. In contrast, PiB became a stronger predictor with time. This is likely due to the trajectory exhibited by amyloid accumulation in the brain, where early in the disease the rate of accumulation is moderate, but around EYO=-15 deposition begins to drastically increase [41]. Overall, these results are consistent with other studies which have shown CSF amyloid markers are the earliest to diverge in MCs compared to NCs, followed by PiB [5]. The third strongest predictor was CSF pT217. Like PiB, CSF pT217 was a moderate predictor early in the disease and became stronger with time, surpassing CSF A β 42/40 as the second-strongest predictor of mutation status. While not as strong as CSF pT217, both CSF pT181 and pT205 were good predictors of mutation status, which has previously been observed [42]. Because measures of amyloid are believed to be the earliest to change in AD, it has been hypothesized that amyloid pathology may lead to an increase in the phosphorylation of tau [43]. It is, therefore, not surprising that these biomarkers were the strongest predictors of mutation status. Lastly, neurodegenerative measures and clinical/cognitive metrics, known to change only in the later stages of the disease, gained predictive strength at EYO \geq 0 (supplementary Figure 5). The weakest predictors of mutation status were GDS, MMSE, FDG, CSF A β 40, serum NFL, and the emerging biomarkers of

neuronal integrity and inflammation. Except for GDS and CSF A β 40, these measures generally group within the neurodegeneration category of the AT(N) framework.

Supplementary Figure 3 shows the trained decision tree and optimal cutoffs used to classify participants by mutation status. PiB, CSF A β 42/40, pT217 ratio, and pT181 ratio gave the optimal results. At the top level, the optimal cutoff for PiB was 1.23. This corresponds to an EYO of -22.2 based on the fitted line shown in Figure 4. If the PiB value was less than this cutoff, CSF A β 42/40 was then evaluated. Interestingly, a participant was classified as mutation positive if the CSF A β 42/40 was greater than .11 ($\text{EYO} \leq -28$). This corresponds to early EYOs where PiB is relatively low ($\text{EYO} \leq -22$) and CSF A β 42/40 is elevated compared to NCs (see Figure 4). Finally, if CSF A β 42/40 and PiB did not meet their cutoffs (EYOs between -28 and -22), a pT217 ratio greater than 1.24 ($\text{EYO} -24$) and a pT181 ratio greater than 23.7 ($\text{EYO} -20$, Figure 5) resulted in a participant being classified as mutation positive.

The relative strength of a biomarker's ability to predict EYO in MC and NC participants is shown in Figure 3. Phosphorylated tau ratios (pT205, pT217, and pT181, Figure 5), CDR-SB, cortical signature, CSF pTau, serum NFL, and CSF YKL40 were the strongest predictors of EYO in MC participants. In NC participants, CSF pTau, serum NFL, and YKL40 were the strongest predictors of EYO. This equates to changes that occurs with normal aging regardless of disease status. Figure 4 and Supplementary Figure 4 show the trajectories for these biomarkers. For each of these biomarkers there was a consistent increase with age in NCs. When compensating for the aging component, the strongest predictors of EYO were pT217, pT205, CDR-SB, and pT181.

These findings have clinical importance for people with ADAD. As the number of biomarkers used to study AD pathology continues to increase, it is important to understand which biomarkers are most reflective of disease pathology. This study is the first to use machine

learning based methods to directly identify how biomarkers cluster, as well as identify the strongest combination of biomarkers that predict mutation status and EYO within each cluster. We have demonstrated that the optimal set of biomarkers can be reduced to a small set of A β and tau measures, and also shown that numerous biomarkers that have gained popularity offer little to no additional information about ADAD pathology when compared to others. This is significant when considering these biomarkers may be used in clinical trials to evaluate the effectiveness of therapies. Further, using our trained decision tree, we can identify biomarker cutoffs, as well as map the cutoffs to specific disease stages, and therefore identify what biomarker is best to use at a specific point in time. This demonstrates the utility of ML in understanding the complex disease progression associated with ADAD that goes beyond group level statistics. Lastly, while identifying mutation status in ADAD can easily be achieved with blood test and EYO calculated based on familial information, the fact that we are able to use this information to identify the optimal set of biomarkers reflective of disease state and pathology is of great importance. Specifically, we believe these results are directly applicable to other forms of AD, such as sporadic AD, where this information is not available.

The main limitation of our study is the use of a cross-sectional research design. Research using prospective designs is needed to further delineate the staging and progression of various biomarkers in relation to EYO. Furthermore, additional variables, such as the specific mutation type should be considered if sufficient numbers are present in future analysis. Alternative forms of feature selection and/or clustering should also be considered to evaluate the relationship among biomarkers and ensure concordance of results. As many A β and tau intervention trials involve participants with ADAD, similar research should be conducted in other genetic forms of AD (e.g. Down syndrome) and late onset AD to ensure correspondence of the biomarker groupings and behavior. Lastly, with the increasing adoption of blood based testing, it is important to evaluate the similarities and differences between blood and CSF biomarkers.

4.1 Conclusion

Understanding the similarities and differences among AD biomarkers, and which biomarkers best represent disease processes, is vital for maximizing the efficiency of clinical trials and patient care. In this study, we have identified three primary cluster of AD biomarkers (neurodegeneration, amyloid/tau, and emerging). Feature selection identified measures of amyloid and tau as the strongest predictors of mutation status, and measures of tau and atrophy as the strongest predictors of EYO. Our analyses also suggest a model for diagnosing ADAD (classifying mutation status) independent of disease stage requires only 4 AD biomarkers (PiB PET, CSF A β 42/40, pT217 and pT181 ratios).

5. Acknowledgements

We would like to acknowledge the participants and their families, without whom these studies would not be possible. We additionally thank all the participating researchers and coordinators (<https://dian.wustl.edu/our-research/observational-study/dian-observational-study-sites/>) who support the studies. DIAN ClinicalTrials.gov identifier: NCT00869817.

6. Funding

This research was funded by the National Institutes of Health (NIH) [grant numbers K01AG053474, K23AG046363, R01AG052550, UFAG 032438, UL1TR000448, P30NS098577, R01EB009352, P50AG05131, U01AG042791, U01AG042791-S1 (FNIH and Accelerating Medicines Partnership), R1AG046179]; the German Center for Neurodegenerative Diseases (DZNE); the National Institute for Health Research (NIHR)

Queen Square Dementia Biomedical Research Centre; and the Medical Research Council Dementias Platform UK [grant numbers MR/L023784/1, MR/009076/1, Alzheimer Association International Research Grant Program #AARFD-20-681815, NSF DMS 156243, DIAN-J by AMED, and an anonymous organization. Further, we acknowledge the support of Fred Simmons and Olga Mohan, the Barnes-Jewish Hospital Foundation, the Charles F. and Joanne Knight Alzheimer Research Initiative, the Hope Center for Neurological Disorders, the Mallinckrodt Institute of Radiology, the Paula and Rodger O. Riney fund, and the Daniel J. Brennan fund.

7. Competing interests

The authors declare no competing interest. Anne Fagan has received research funding from the National Institute on Aging of the National Institutes of Health, Biogen, Centene, Fujirebio and Roche Diagnostics. She is a member of the scientific advisory boards for Roche Diagnostics and Genentech and consults for Diadem, DiamiR and Siemens Healthcare Diagnostics Inc. Carlos Cruchaga receives research support from Biogen, Eisai, Alector, and Parabon. The funders of the study had no role in the collection, analysis, or interpretation of data; in the writing of the report; or in the decision to submit the paper for publication. Dr. Cruchaga is also a member of the advisory board of ADx Healthcare, Halia Therapeutics, and Vivid Genomics. Jasmeer P. Chhatwal served on the medical advisory board for Otsuka Pharmaceuticals. Johannes Levin reports speaker's fees from Bayer Vital, speaker's fees from Willi Gross Foundation, consulting fees from Axon Neuroscience, consulting fees from Ionis Pharmaceuticals, author fees from Thieme medical publishers and W. Kohlhammer GmbH medical publishers, compensation for work as part-time CMO from MODAG GmbH, and non-financial support from AbbVie outside the submitted work. John Morris is funded by NIH grants [numbers P50AG005681, P01AG003991, P01AG026276, UF1AG032438]. Dr. Jack

1 serves on an independent data monitoring board for Roche and has served as a speaker for
2 Eisai, but he receives no personal compensation from any commercial entity. He receives
3 research support from NIH and the Alexander Family Alzheimer Disease Research
4 Professorship of the Mayo Clinic. Eric McDade is involved in a clinical trial on AV-1451
5 sponsored by Avid and serves on a data safety monitoring committee for Eli-Lilly and Alector
6 and is on the Scientific Advisory Board for Alzamend; research support from Eli-Lilly and
7 Hoffman-La Roche. Dr. McDade is a co-inventor of the “Methods of diagnosing AD with
8 phosphorylation changes” technology licensed by Washington University to C2N Diagnostics.
9 Washington University also holds 5% equity in C2N. Through these relationships, Washington
10 University and Dr. McDade are entitled to receive royalties from the license agreement with
11 C2N. Dr. David Holtzman, Chair of Neurology at Washington University Medical School, is
12 a co-founder of C2N and serves on C2N’s advisory board. Randall Bateman is on the scientific
13 advisory board of C2N Diagnostics and reports research support from AbbVie, Biogen, Eisai,
14 Eli Lilly, Co/Avid Radiopharmaceuticals, Roche, Janssen, and United Neuroscience. Dr.
15 Weiner receives support for NIH grants: 5U19AG024904-14; 1R01AG053798-01A1; R01

Figure legends

Figure 1. At the highest level, biomarkers grouped by neurodegeneration (yellow), amyloid and tau (blue), and emerging biomarkers of neuronal integrity and inflammation (green). The amyloid/tau cluster encompassed amyloid PET (PiB), CSF A β 40 and A β 42/40, and all CSF tau measures, including tau mass spectrometry ratios (pT217, pT181, pT205) and Lumipulse total tau and total pTau (C tTau, C pTau). The neurodegeneration cluster included measures of metabolism (FDG), atrophy (CorSig), serum NfL, and cognitive assessment measures. The final cluster consisted of the emerging biomarkers of neuronal integrity and inflammation as well as CSF A β 40. Of note, depression (GDS) was separate from the other measures.

Figure 2. The strongest predictors of mutation status with regards to estimated years to symptom onset (EYO). Features were calculated for a sliding 15-year window that incremented 1 year at a time that encompassed EYOs between -25 and +10. Red line indicates 15-year window that was centered at EYO of 0 (± 1 year). The strongest predictors of mutation status were amyloid markers (CSF A β 42/40, PiB, and pTau 217 ratio). CSF A β 42/40 and PiB showed an inverse trajectory. CSF A β 42/40 was the strongest predictor early in the disease process followed by a relative decrease later in the disease course. In contrast, PiB was a slightly weaker predictor earlier in the disease process but gradually increased in predictive strength later in the disease course. Results coincide with the predictive strengths of each of the measures when not using a sliding window and all EYOs were combined into a single analysis (see supplemental Figure 2).

Figure 3. Strongest predictors of EYO for mutation carriers (MC) and non-carrier (NC) participants. Overall, the strongest predictors for MC participants were phosphorylated tau mass spectrometry ratios (pT205, pT217, pT181). YKL40 and serum neurofilament light (NfL) were strong predictors for both MC and NC participants, suggesting a strong aging component regardless of disease pathology (see Figure 4 and 6 bottom right for trajectories).

Figure 4. Trajectories for biomarkers of amyloid, tau, and neurodegeneration (AT(N)) for NC (blue) and MC (red) from -20 to +10 EYO. Trajectories for amyloid biomarkers (PiB, CSF A β 42/40), tau (Lumipulse CSF total tau and CSF total pTau [181]), and neurodegeneration (cortical signature and serum NfL) were fit using a 2-degree polynomial with shaded regions representing standard error. Differences between MC and NC were observed early for amyloid and tau (-20 to -15 EYO). Differences were also observed between MC and NC for

neurodegeneration markers but were closer to EYO (-10 to -5 EYO). Of note, changes in cortical signature and serum NfL were seen with aging regardless of mutation status.

Figure 5. Trajectories for CSF mass spectrometry phosphorylated tau ratios pT217, pT181, and pT205 for NC (blue) and MC (red) from -20 to +10 EYO. Trajectories were fit using a 2-degree polynomial with shaded regions representing standard error. For both CSF pT217 and CSF pT181 changes were seen very early (20 EYO), while changes in CSF pT205 occurred slightly later.

Table 1. Demographics

	Mutation carriers (MC)	Mutation-negative non-carriers (NC)	p-values
N	130	79	
Age (years) ± SD	39.9 ± 10.7	41.7 ± 11.3	.24
Sex (% Male)	45%	39%	.39
Race (% Caucasian)	92%	92%	.98
Education (years) ± SD	14.6 ± 3.1	14.8 ± 2.3	.62
EYO (years) ± SD	-6.6 ± 9.8	-5.5 ± 11.5	.48

Abbreviations: SD, standard deviation; EYO, estimated years until symptom onset.

Systematic review: The authors reviewed the literature using traditional (e.g., PubMed) sources and meeting abstracts and presentations. Relevant citations are included where appropriate.

Interpretation: Our findings suggest that biomarkers of autosomal dominant Alzheimer disease (ADAD) can be grouped into three primary clusters: neurodegeneration, amyloid/tau, and emerging biomarkers of neuronal integrity and inflammation. Further, the primary predictors of ADAD status consist of amyloid and tau measures, while the emerging biomarkers of neuronal integrity and inflammation are relatively weak predictors.

Future directions: Future work will focus on (a) performing similar analysis in other forms of Alzheimer disease (e.g., Down syndrome and sporadic Alzheimer disease) to ensure correspondence of the biomarker groupings and behavior, and (b) perform the analysis on longitudinal data.
