Abstract

The application of CCS in the iron and steel industry faces particular challenges for achieving European CO₂ transportation and storage in meeting CO₂ stream impurity limit specifications due to the unique and diverse composition of the steelworks off-gases targeted for CO₂ capture and the separation efficiency of proposed CO₂ capture solutions. This paper reviews the range and levels of compounds that could form potential CO₂ impurities in steelworks off-gases and provides estimates of the quality of CO₂ products obtained in primary CO₂ capture steps from Blast Furnace Gas (BFG) using different technologies of Pressure-Swing Adsorption (PSA) and amine scrubbing. Published CO₂ specifications from European transportation and storage operators are reviewed and compared. Additional suitable purification steps that are needed in order to reduce the levels of impurities from primary CO₂ product streams in order to achieve European CO₂ impurity limit specifications are identified, characterised and the associated cost implications discussed.

Keywords: CCS, CO₂ Quality, Iron & Steel, Impurities, CO₂ Purification

1. Introduction

The iron and steel industry represents the largest energy consuming manufacturing sector in the world, with average specific emissions being around 1.83 tonnes of CO₂ per tonne of all crude steel produced and global crude steel production reaching 1.86 Gt for the year 2020. The CO₂ footprint of steel mills accounts for up to 8% of anthropogenic emissions.

A unique feature of the current steel making processes is the presence of energy containing off-gases, with the three main being Coke Oven Gas (COG), Blast Furnace Gas (BFG) and Basic Oxygen Furnace Gas (BOFG). Conventionally, these off-gases are used to fuel reheating furnaces or for power generation, but are increasingly now targets for the application of Carbon Capture and Storage (CCS). CO₂ capture strategies for steelworks off-gas application aim to separate CO₂ while producing another energy containing gas stream for further use with much reduced carbon content. The general characteristics of the steelworks off-gases are shown in table 1. COG is the most energy rich of these streams containing ~65 vol% H₂ while the BOFG has significant CO content (>50 vol%). BFG represents the greatest volumetric flow, and is hence the focus of particular attention for CCS application, but has a low energy content, consisting of ~50-60 vol% N₂ and ~20 vol% CO₂.

The fate of the main steelworks off-gas components and a range of other contaminants when CCS systems are applied, and the degree to which these will carry over into CO₂ product streams to form impurity compounds, is an important issue for the iron and steel industry. Impurities also need to be accounted for when capturing CO₂ from many other emitting industries (e.g. cement, waste-to
energy, refineries etc.). This is because the anticipated impurities can have a range of mainly deleterious impacts on different parts of the CCS chain (i.e. on the capture process and compression/liquefaction equipment, CO₂ transportation infrastructure (pipeline and/or ship tanker), CO₂ injection well and geological storage sites). These impurity impacts include toxic effects on humans, corrosion effects on metals, metal embrittlement, along with effects on hydraulic efficiency, pipeline fracture behaviour, geological storage capacity and geochemistry (e.g. mineral dissolution and precipitation). CO₂ impurity impacts have received attention from the CCS scientific community [2][3], with some operational experience gained from CO₂ Enhanced Oil Recovery (EOR) [4]. The CO₂QUEST project [5] reviewed typical compositions of CO₂ streams from CCS and provided experimental results for the effect of impurities on pipeline rupture and CO₂ dispersion behaviour using extensively instrumented realistic-scale pipeline test facilities. Experimental and modelling results for the geological impact of impure CO₂ were also obtained while full-chain CCS techno-economic tools were developed.

In view of the impacts of CO₂ impurities, CO₂ transportation and storage providers set concentration limits for impurities, meanwhile other authors propose to determine CO₂ stream composition based on a case specific multi-criteria optimisation. Despite a significant body of knowledge acquired, the fate and impact of impurities in CCS still requires an improved understanding and characterisation in order to facilitate technology roll-out, especially in consideration of the widening scope of applications and development of future generations of CO₂ capture technologies. Research is also needed on the associated cost benefit analysis of CO₂ purification while simultaneously considering the operational and safety aspects surrounding the potential for co-transportation/storage of CO₂ impurities.

In this paper, the range and level of impurities in steelworks off-gases are reviewed and the propensity of components to form impurities in the product streams from different primary CO₂ capture steps, including Pressure-Swing Adsorption (PSA) and amine based systems, is assessed. Following a review of current European CO₂ stream transportation and storage specifications, the requirements for the application of additional CO₂ stream clean-up technologies are identified and assessed.

2. Potential impurities in steelworks off-gases

The application of CCS to steelworks off-gases can result in new challenges due to the presence of a high number of different impurities as compared to other industrial emitters which use natural gas as a feedstock or fuel. In addition to the main components listed in table 1, other impurities may be present in low concentrations (in the parts per million (ppm) or parts per billion (pppb) region). The main compounds and their categories have been summarised by Schmittkowski et al. [6] and are shown in table 2. Some of these compounds have known toxic effects on humans (e.g. mercury (Hg)) while others pose corrosion concerns to metals, especially when present in mixtures with water (e.g. hydrogen sulfide (H₂S), which is also poisonous and flammable, and sulfur oxides (SOₓ)).

A small number of literature resources give details of the concentration levels of impurity compounds in steelworks off-gases. The most comprehensive of these, which also includes the state-of-the-art in the purification of steelworks off-gases, is the European Commission (EC) document “Best Available Techniques (BAT) Reference Document for Iron and Steel Production” [7]. Levels of impurity compounds in steelworks off-gases vary in different plants depending on a variety of considerations including the age of the plant and operational factors, such as the degree of pollution removal technologies employed and the type of coal selected for coke production (e.g. low or high sulfur coal). Table 3 shows the concentrations of some impurity compounds reported in [7]. BFG is known to contain different levels of H₂S; 14 mg/Nm³ given in table 3 is equivalent to 10 ppm, which is in the lower range of other reported ranges. For example, Bender et al [8] report H₂S to be present in BFG in the range of 10–40 mg/m³. More recently, Lanzierstorfer et al. [9] measured a range of gaseous components in BFG emissions and characterised the top scrubber efficiency; they found that the clean gas emission of sulfur was dominated by carbonyl sulfide COS (at 279 mg/m³ (standard temperature and pressure - STP)) which accounted for about 85% of the total sulfur emissions, while H₂S and SO₂ accounted only for 15% and 0.6%, respectively. Although no data is available in the EC BAT document, the nitrogen containing species, HCN and NH₃ are believed to be present in BFG, but levels in the clean gas are believed to be low at 0.12 and 0.15 mg/m³ (STP), respectively, according to the recent measurements [9]. Low levels of heavy metals Mn, Pb and Zn are also reported for BFG in table 3. Compounds other than those reported for BFG in table 3 may be

n/a: data not available; LS: (crude) Liquid Steel; BTX: Benzene, Toluene and xylene isomer;

present such as O$_2$ and CH$_4$, in addition to low levels of HCl, BTX and other smaller hydrocarbons. It is also worth noting that large time-dependent fluctuations in the compound concentrations may occur during steelworks operations [10], hence the presented values may be considered as average. As also shown in table 3, COG can contain some similar inorganic compounds as BFG (i.e. sulfur compounds, NH$_3$, HCN), and typically contains a wide range of light and heavy hydrocarbons. COG is typically cleaned before being used as fuel in a steel plant, to remove dust, tar, naphthalene, light oil, sulfurous compounds and the cracking of ammonia to hydrogen [11]. BOFG is known to contain levels of dust and NO$_x$, as well as low levels heavy metals (Mn, Pb, Cr, Cu), PAH and very low amounts of PCCD/F.

3. Impurities in CO$_2$ streams produced by capture from BFG

For a better understanding of the implications of impurities present in steelworks off-gases on CCS systems, estimates have been made of their levels in CO$_2$ streams captured from BFG using a mass balance technique applied to a generic CO$_2$ capture scheme shown in figure 1(a). Figure 1(b) also shows the case for a CO$_2$ capture and conversion process which can be achieved using technologies such as Sorption Enhanced Water Gas Shift (SEWGS) [11] or Calcium Assisted Steel-mill Off-gas Hydrogen (CASOH) technologies [12].

Table 4 provides the estimated concentrations of major impurities for two different CO$_2$ capture technologies that are considered here: PSA and amine based systems. The performance of the PSA system is based on that reported during pilot scale trials in the COURSE50 project using the Zeolium F-9H sorbent, in terms of CO$_2$ purity and recovery rates achieved [13]. Two PSA cases are presented comprising a low purity case, based on a CO$_2$ purity of 83 mol% and recovery of 67%, and a high purity case based on 99.5 mol% purity and 61% recovery.
Based on the typical behaviour of PSA systems, the sulfur species (i.e., COS, H$_2$S and SO$_2$) are assumed to enrich in the CO$_2$ product (adsorbate) and therefore partition completely. All other species are assumed to distribute evenly between the non-CO$_2$ portion of the CO$_2$ rich stream and the CO$_2$ lean streams exiting the PSA system since they have lower molecular weights. It should be noted that in the pilot-scale system testing [13], a desulphurisation unit was included prior to the PSA system, whereas this stage is neglected in the current analysis. The estimation of the CO$_2$ composition captured from BFG using an amine system is based on the laboratory based analysis reported by Dreillard et al [14] for monoethanolamine (MEA) and DMX solvents, which achieved CO$_2$ purity set at 99.7 mol% (dry basis) and a CO$_2$ capture rate of 90%. The concentration of CO was reported to be 375 ppm, in the stripper top in the case of capture using MEA applied to an inlet gas representative of Top Gas Recycling (TGR) conditions with a composition of CO$_2$=37.04 mol%, CO=46.71 mol%, N$_2$=9.21 mol%, H$_2$=7.04 mol%, hence the value used in table 4 is proportionally scaled to account for the lower inlet concentration of CO in the typical BFG case. The concentration of amine in the CO$_2$ product is also based on the reported value by Dreillard et al for the TGR case. In the MEA case, sulfur containing compounds, nitrogen containing contaminants (NH$_3$ and HCN) and HCl are all assumed to partition completely with CO$_2$. HCN and SO$_2$ may form heat stable salts and COS may also undergo hydrolysis in amine systems [15]. The values presented here for the MEA case may therefore represent conservatively high estimates for contaminant concentration and actual values require a thorough investigation through experimental measurement.

4. European specifications for CO$_2$ transport and storage

Three European specifications for CO$_2$ transportation and storage have recently been published from the Northern Lights CCS project [16], National Grid in the UK [17] and TAQA for the PORTHOS project [18]. The Northern Lights project is part of the Norwegian full-scale CCS project, which includes the capture of CO$_2$ from industrial sources beginning in the Oslofjord region; the CO$_2$ will be liquified and shipped to a Northern Lights facility near Bergen, where it will be pumped 2,600 meters below the sea floor into a saline aquifer. The National Grid CO$_2$ specification has been developed since 2009 in the context of the UK Government’s CCS commercialization competitions and has been based largely on the specification provided by the DYNAMIS consortium, with some adjustments for some compounds such as H$_2$S to ensure the pipelines do not become classified as “sour service” and the water level to prevent material degradation. The PORTHOS project associated to TAQA’s CO$_2$ specification, will use depleted gas fields in the North Sea to store CO$_2$ which will be captured from industrial emitters in the Port of Rotterdam area and transported by pipelines. Table 5 shows the CO$_2$ specification provided in these three resources. For the comprehensive breakdown of the rationale behind the proposed limits for each component in the three specifications, the reader is referred to the relevant reports [16][17][18].

Comparing the different specifications, it can be seen from table 5 that similarities and differences exist. TAQA’s specification is the most comprehensive with precise recommendations provided for 21 components. The Northern Lights specification provides recommendation for amine and potential degradation products (NH$_3$, formaldehyde, acetaldehyde) and, generally, sets the most stringent limits on all components barring NO$_x$, H$_2$S and HCN. The National Grid minimum concentration for CO$_2$ is 96% for dense phase CO$_2$ which is broadly in-line with the TAQA recommendation where the sum of non-condensable components must not exceed 4 vol%. No specific lower limit is set for CO$_2$ in the Northern Lights specification but non-condensables will be limited by their solubility in liquid CO$_2$ during interim storage. In all three specifications, tight limits are set for H$_2$O (30-50 ppmv) and O$_2$ (10-40 ppmv), while limits for NO$_x$ range from 5 to 100 ppmv. Some variation is observed between the three specifications in the case of sulfur species; TAQA’s limit for H$_2$S is lowest at 5 ppmv, followed by the 10 ppmv limit for Northern Lights and 80 ppmv, gas and the 20 ppm dense phase National Grid limits. These H$_2$S limits are in contrast to the composition of transported CO$_2$ in North America for the purposes of EOR in the Weyburn Project, where around 0.9 vol% H$_2$S is co-injected into an oil reservoir. H$_2$S is known to have a beneficial effect for EOR due to the reduction of the minimum miscibility pressure for CO$_2$ and oil mixtures, while a range of other factors such as population density are considered to account for differences in the limits on H$_2$S between North American and European CO$_2$ transportation and storage applications. National Grid’s limit on H$_2$S was selected to avoid selection of pipeline materials for sour service. Variation in the permitted concentrations of SO$_2$ is also observed between specifications with Northern Lights being the lowest at 10 ppmv and National Grid having the highest at 100 ppmv. Only TAQA gives specific low limits for COS (at 0.1 ppmv) and (CH$_3$)$_2$S (at 1.1 ppmv). A large disparity on the limits for hydrogen is observed with a limit of 50 ppm, imposed in the case of Northern Lights but much higher tolerances for National Grid at 2 vol% and TAQA at 0.75 vol%. A notable disparity also exists in the case of CO where at National Grid and TAQA allow up to 2000 and 750 ppmv, respectively, but Northern Lights has the tightest restriction at 100 ppmv.

Given the types and levels of impurities expected in CO$_2$ streams captured from BFG presented in table 4 and the limits imposed for impurities in the CO$_2$ specifications of table 5, insights can be gleaned into which components may be problematic for the iron and steel industry in meeting the CO$_2$ purity requirements for the associated transportation and storage infrastructure. Notably, that in the PSA cases, CO is an issue and will need to be significantly reduced in order to meet any of the specifications. Even the CO$_2$ captured by the amine
system which has the lowest content of CO estimated at 200 ppmv will not meet the 100 ppmv threshold for the Northern Lights specification. Other potentially problematic impurities include reduced sulfur compounds, H₂S and COS. Reductions in the content of H₂S in CO₂ for all PSA and amine capture systems appears to be needed while a drastic reduction in COS would be required to meet the TAQA specification. Issues related to SO₂ would appear to be less of a concern where all three estimated capture qualities would already meet the required threshold for all CO₂ specifications. Similarly, the nitrogen containing impurities, HCN and NH₃ appear not to need specific targeting by additional separation. To meet the strict limits on water concentration, it is clear that some form of dehydration will be needed to reduce the amounts from saturated levels from the capture systems, although this should not be of great concern due to available technologies being mature and inexpensive. Other potential impurities of concern include H₂ in the case of meeting the Northern Lights specification and O₂ where air ingress may take place in iron and steel plant or CO₂ capture systems. O₂ may also become a problematic impurity in species for other types of technologies that could be employed for CO₂ capture on iron and steel plants such as those that use oxy-combustion based approaches. In the following section, we discuss approaches that can be taken to reduce the impurities of concern in the captured CO₂ from BFG streams.

5. CO₂ purification approaches

In this section, approaches to CO₂ purification suitable for CO₂ capture from BFG are discussed with emphasis on targeting the critical contaminants, reduced sulfur species and CO. Multicomponent removal solutions are also outlined.

5.1 Approaches to H₂S and COS reduction

Sulfur components can be removed either by wet scrubbing or by dry adsorption processes. In wet processes, the sulfur components can be removed by physical (e.g. Rectisol) or chemical adsorption (e.g. MEA) or by a combination of both. An example of a dry
process is the adsorption of H₂S on ZnO [19]. Technologies for sulfur reduction should be selected on the basis of inlet and target concentration, while scale is another important factor. Wet processes are characterised by high investment costs and are therefore mainly used at large scale. Dry processes are used mainly for low inlet concentrations and therefore may be suitable for targeting the levels of sulfur in BFG. The ZnO adsorbent process is widely used for H₂S removal (at levels normally <50 ppm) from natural gas or syngas at temperatures of 200−450°C. In a conventional catalytic adsorbent purification system, illustrated in Figure 2, ZnO is used in conjunction with hydrogenation catalysts based on cobalt, molybdenum and nickel. This system involves the hydrogenation of sulfur compounds such as mercaptans to H₂S, and halides such as chlorides to HCl. These compounds are then reacted with the ZnO absorbent where H₂S is converted to zinc sulfide, and HCl forms a stable chloride. Additionally, ZnO removes COS by hydrolysis to form H₂S which is then adsorbed to form zinc sulfide [20]. The general, reactions are summarised as follows:

**Hydrogenation reactions:**

\[
\text{RSH} + \text{H}_2 \rightarrow \text{RH} + \text{H}_2\text{S}
\]

\[
\text{RCl} + \text{H}_2 \rightarrow \text{RH} + \text{H}_2\text{S}
\]

**Reactions with ZnO:**

\[
\text{ZnO} + \text{H}_2\text{S} \rightleftharpoons \text{ZnS} + \text{H}_2\text{O}
\]

\[
\text{ZnO} + \text{COS} \rightleftharpoons \text{ZnS} + \text{H}_2\text{O}
\]

Figure 2: Conventional ZnO purification system [20].

Sulfur removal below 50 ppb, is attainable with ZnO. However, a hydrogenation reactor may not be required in the case of processing BFG if the presence of halogens and sulfur compounds other than H₂S and COS is not a concern for the downstream impacts. A quantity of 100 kg ZnO is required to remove 39 kg S while the cost of a ZnO sorbent is ~2 $/kg.

5.2 Approaches to CO reduction

Different approaches can be taken for reducing the CO content in captured CO₂ streams that may once again depend on the quantities involved, the inlet and target concentrations. In the case of low purity CO₂ from the PSA based capture case with 83% purity CO₂, a cryogenic based system is an option to remove CO simultaneously with other non-condensable components. In such a system, CO₂ is liquefied to separate it from the non-condensable gases. The ULUCOS program [21] explored the use of PSA and vacuum PSA (vPSA) systems with a subsequent cryogenic separation for achieving high purity CO₂. Cryogenic flash separation is commonly used to treat CO₂ streams with above 80 mol% purity. Higher grades of CO₂ can be produced using cryogenic distillation which have a history of development for oxyfuel combustion power systems, and operate at elevated pressures ~30 bar and low temperatures between -10 °C and -60 °C. The conditions in this process make it energy intensive with an energy requirements for the CO₂ Compression and Purification system (CPU) ranging from of 412 to 700 kJ/kgCO₂. Typical recovery efficiencies are in the range of 86.6 to 90.1% with CO₂ purities as high as 99.99 vol% achievable [22].

Other approaches to CO reduction can involve conversion by reaction to other compounds which are more easily separable or have higher thresholds in the CO₂ specifications. For example, the water gas shift process could be used to convert CO to CO₂ and H₂ but would necessitate both high and low temperature conversion units for deep CO reduction. Employing this process could also lead to improved overall CO₂ capture rates above 80%. Alternatively, CO could be reacted with H₂ to produce CH₄ or with O₂ to produce CO₂. Oxidation as an approach to CO reduction is covered below in the context of multi-component removal approaches.

5.3 Approaches to multicomponent reduction

Catalytic oxidation has been used as an approach to remove ppm levels of impurities from raw CO₂ streams to produce high purity CO₂ product for different applications including for the food industry. Praxair patented a technology for the removal sulfur compounds and hydrocarbons from CO₂ which is also capable of CO reduction [23]. This technology uses a sulfur tolerant catalytic oxidation system whereby contaminants are oxidised to CO₂, water and SO₂ which are then removed by adsorption and/or absorption techniques. While hydrocarbons are converted to CO₂ by the catalytic oxidation process, sulfur compounds (e.g. H₂S, CS₂, COS and mercaptans) present in the CO₂ stream react with O₂, forming their respective combustion products according to the following reactions:

\[
2\text{H}_2\text{S} + 3\text{O}_2 \rightarrow 2\text{SO}_2 + 2\text{H}_2\text{O}
\]

\[
\text{CS}_2 + 3\text{O}_2 \rightarrow 2\text{SO}_2 + \text{CO}_2
\]

\[
2\text{COS} + 3\text{O}_2 \rightarrow 2\text{SO}_2 + 2\text{CO}_2
\]

\[
\text{CH}_3\text{SH} + 3\text{O}_2 \rightarrow \text{SO}_2 + \text{CO}_2 + 2\text{H}_2\text{O}
\]

Figure 3 presents a simplified process block flow diagram for the purification system by catalytic oxidation. Crude CO₂ first passes through a compression step and liquid water is removed by a separator. In this system, O₂ is injected either as air or PSA produced O₂ to maintain an excess O₂ concentration of approximately 1000 ppm in the gas stream leaving the catalytic
oxidation reactor. The temperature of the gas entering the

catalytic reactor is increased to approximately 315 to 480
°C and then passed over a sulfur tolerant metal catalyst
(platinum and palladium catalysts are preferred) where

the impurities react with the O₂ to form oxidised
products. The temperature of the catalytic bed is typically
kept below about 425 °C to minimise the oxidation of
CH₄ since this contaminant can readily be removed in a
subsequent CO₂ liquefaction/stripper stage. The catalytic
oxidiser is operated at a preferred pressure of about 17 to
22 bar. After the hydrocarbon contaminants and the
sulfur compounds are converted to their respective
oxides, upon exiting the catalytic oxidiser, the gas stream
is cooled by means of a cooler/condenser and condensed
water is removed using a water separator. The sulfur
oxides are next subsequently removed from the CO₂
stream by absorption, for high concentrations of sulfur
components (e.g. ~100-5000 ppm), or by adsorption, for
low concentration of sulfur components (e.g. ~1-100
ppm). The gas stream (which now is free of sulfur,
hydrocarbon compounds and water) enters the CO₂
liquefier, where the non-condensables (e.g. O₂, N₂ and
CH₄) are separated by distillation and vented from the
liquid CO₂ stream. The process is claimed to produce
CO₂ at a quality of 99.9 vol% CO₂ with N₂ < 60 ppmv, O₂
< 30 ppmv, sulfur species < 1 ppmv, total hydrocarbons
<20 ppmv and water < 20 ppmv, and at a temperature of
-18 °C and pressure of 10 bar.

![Block flow diagram of CO₂ purification process by catalytic oxidation](image)

Other embodiments of the above process have been
proposed where the excess O₂ is chemisorbed by a bed of
transition metal adsorbent (i.e., Cu or Ni) in place of a
distillation system, or where the excess oxygen leaving
the catalytic oxidation system is controlled to less than
30 ppmv by using a “tight control” option [23].

At the time of writing, no detailed techno-economic
studies of CO₂ purification by catalytic oxidation for
removal of CO and sulfur components are available in the
literature.

5.4 Water removal technologies

Dehydration of CO₂ streams can be carried out using
several technologies, including compression and cooling,
adsorption using solid desiccants, absorption using liquid
desiccants, absorption with a deliquescent solid, and
cooling below the initial dew point [24].

Guidelines for the selection of dehydration technology
for carbon capture systems have been put forward by
Kemper et al. [25] which allocates a range of

technologies, such as TEG (triethylene glycol) and
molecular sieve systems, applicable to certain ranges of
wet gas water content and a target dry gas concentrations.

These authors also noted that the presence of impurities,
i.e. NOₓ, SOₓ and H₂S, leads to a 7% higher capital
expenditure (CAPEX) but no difference in operational
expenditure (OPEX) for molecular sieve systems. For the
iron and steel industry, the derived CO₂ product streams
presented in table 4 and the target concentrations of
European CO₂ specifications listed in table 5, molecular
sieve and silica gel systems are the most likely

technologies for implementation.

6. Conclusion

This paper has reviewed the range and level of impurity
components in steelworks off-gases and provided
estimates of their carry over into CO₂ product streams
when primary capture steps of PSA (low and high purity
scenarios) and amine scrubbing are applied to BFG.

While useful insight can be gleaned from these estimates,
they require further assessment by experimental
investigation and detailed process simulation studies.
European CO₂ transportation and storage specifications
have been reviewed and compared, with the implications
for the impurity content of CO₂ streams captured from
BFG. In many cases, additional gas clean-up measures
will likely be needed if the CO₂ specifications for
impurity limits that are currently imposed by CO₂
transportation and storage providers are to be met.

Particular CO₂ impurities of concern that require
reduction for the presented applications of CCS in the
iron and steel industry are CO and the reduced sulfur
species H₂S and COS. Dehydration systems will also be
needed for CO₂ product processing. Options for
removing sulfur components suitable for the levels
present in BFG focus on adsorption based systems, while CO reduction techniques for impure CO₂ involve cryogenic separations. Multicomponent removal methods for CO and sulfur species involve catalytic oxidation followed by adsorption/absorption and cryogenic separation.

It should be noted that reasonable limits on impurities in CO₂ must be set on the basis of safety, design, operation, integrity and hydraulic efficiency of the associated transportation and storage infrastructure and these requirements have to be considered as a whole. Thresholds which are excessively stringent for impurities in CO₂ transportation and storage specifications will cause a financial burden on CO₂ emitters due to the associated costs of removal, therefore posing a potential barrier to CCS deployment. Conversely, the emission of high levels of impurities in CO₂ product streams into infrastructure could move the financial burden onto transportation and storage providers. Techno-economic analysis techniques should be employed to consider site-specific design and operation of the CCS chain during normal and abnormal operation in order to achieve an optimised balance between the cost of purification and the impacts of impurities on CO₂ transportation and storage infrastructure.
