ABSTRACT

Background Neurofilament light (NFL) is a widely used biomarker for neurodegeneration. NFL is prone to oligomerisation, but available assays do not reveal the exact molecular nature of the protein variant measured. The objective of this study was to develop a homogeneous ELISA capable of quantifying oligomeric NFL (oNFL) in cerebrospinal fluid.

Methods A homogeneous ELISA, based on the same capture and detection antibody (NFL21), was developed and used to quantify NFL in samples from patients with behavioural variant frontotemporal dementia (bvFTD, n=28), non-fluent variant primary progressive aphasia (nfvPPA, n=23), semantic variant PPA (svPPA, n=10), Alzheimer’s disease (AD, n=20) and healthy controls (n=20). The nature of NFL in CSF, and the recombinant protein calibrator, was also characterised by size exclusion chromatography (SEC).

Results CSF concentration of oNFL was significantly higher in nfvPPA (p<0.0001) and svPPA patients (p<0.05) compared with controls. CSF oNFL concentration was also significantly higher in nfvPPA compared with bvFTD (p<0.001) and AD (p<0.001) patients. SEC data showed a peak fraction compatible with a full-length dimer (~135 kDa) in the in-house calibrator. For CSF, the peak was found in a fraction of lower molecular weight (~53 kDa), suggesting dimerisation of NFL fragments.

Conclusions The homogeneous ELISA and SEC data suggest that most of the NFL in both the calibrator and human CSF is present as a dimer. In CSF, the dimer appears to be truncated. Further studies are needed to determine its precise molecular composition.

INTRODUCTION

Neurofilament light (NFL) is a 68 kDa type IV intermediate filament with structural functions in the neuronal cytoskeleton, mainly found in axons. Under physiological conditions, there is a basal release of NFL into the cerebrospinal fluid (CSF), which increases with age. However, after axonal damage in neurodegenerative conditions and other acute neurological conditions such as traumatic brain injury or stroke, its release greatly increases. Previous studies indicate NFL as a general marker of neurodegeneration, with its concentration in CSF and blood being increased in several neurological diseases including Alzheimer’s disease (AD), multiple sclerosis (MS), amyotrophic lateral sclerosis, Huntington’s disease and frontotemporal dementia (FTD). NFL is a well-established biomarker for neurodegeneration and several assays, either immunoassay or mass spectrometry (MS) based, have previously been developed intended to quantify it in body fluids. In a recent study, Budelier et al showed that, in CSF, no full-length NFL was found. Instead, it was detected by immunoprecipitation-MS analysis as various truncated species, shedding some light on the actual molecular state of this protein in CSF.

The hypothesis in this study is that NFL could be present in CSF as an oligomer. Our goal was to develop a homogeneous ELISA, using the same capture and detection antibody, to test this hypothesis and to quantify these oligomers in CSF. We also set out to examine the apparent size of NFL by size exclusion chromatography (SEC) in CSF and the calibrator used in the ELISA.

METHODS

Participants
This study included FTD patients (n=61) from different variants, including behavioural variant FTD (bvFTD, n=28), non-fluent variant primary progressive aphasia (nfvPPA, n=23) and semantic variant primary progressive aphasia (svPPA, n=10). Among the FTD patients, 17 were mutation carriers affecting...
progranulin (GRN), chromosome 9 open reading frame 72 (C9orf72) or microtubule-associated protein tau (MAPT) and 44 were sporadic cases from the University College London Genetic FTD Initiative (GENFI) and Longitudinal Investigation of FTD (LIFTD) studies. Assessment was performed based on standardised history and Longitudinal Investigation of FTD (LIFTD) studies. The analysis was performed using GraphPad Prism software, V.9.4.1.

Data are shown as median (IQR). One-way ANOVA was applied to all study subgroups.

Size exclusion chromatography
SEC was performed using an Etta Chromatography System (Amersham Biosciences) equipped with a Superdex 200 10/300 GL column (GE Healthcare) connected to a fraction collector (Fracto-500, Amersham Biosciences). The column was equilibrated with a 10 mM ammonium bicarbonate buffer, which was also used in the isocratic separation. Injected sample volume was 500 µL and the flow rate 0.5 mL/min, while the fractions collected were 1 mL. Calibration of the column was performed using gel filtration markers (Sigma, MWGF70).

Statistical analysis
One-way analysis of variance with Tukey’s test correction was used to determine significant differences between groups, with p<0.05 considered statistically significant. The analysis was performed using GraphPad Prism software, V.9.4.1.

RESULTS
CSF oNFL group differences
Two homogeneous setups with the in-house monoclonal antibodies were tested, namely NIL21+NIL21 and NIL23+NIL23. Both assays correlated strongly (r=0.9913, p<0.0001, online supplemental figure 1) with the only
difference being the slightly higher concentration obtained with the NfL21 setup, which was the assay selected for further testing.

To assess any differences in oNfL concentrations, samples representing several neurodegenerative diseases were included in a pilot study. All samples were randomised and analysed blinded, under the same conditions. Results showed significant increases in oNfL concentrations in nfvPPA (2.90e+4 ± 4.66e+3 pg/mL, p<0.0001) and svPPA (2.36e+4 ± 3.24e+3 pg/mL, p<0.05) compared with controls (8.50e+3 ± 8.22e+2 pg/mL). nfvPPA also displayed increased oNfL compared with bvFTD (1.35e+4 ± 1.72e+3 pg/mL, p<0.001) and AD (1.30e+4 ± 2.74e+3 pg/mL, p<0.01). However, neither bvFTD nor AD had any significant differences compared with controls (figure 1A).

**Size exclusion chromatography**

SEC analysis of in-house calibrator showed a peak fraction (~135 kDa) that was consistent with full-length NfL dimers (figure 1B). Still, in CSF, the peak was found in fractions corresponding to lower molecular weight (~53 kDa), suggesting that oligomers in CSF are formed of truncated NfL (figure 1C).

**DISCUSSION**

This study shows that most NfL in CSF and the assay calibrator is a multimer (likely a dimer). None of the currently used NfL immunoassays give any information regarding the multimeric state of the protein. In the newly developed homogeneous assay, where the capture and detector antibodies are the same, the binding of the capture antibody to the target protein blocks the epitope for the detector antibody, thus nullifying the output signal if the captured protein is in monomeric form. However, if the captured protein is in oligomerised form, there will still be epitopes available for detector antibody-binding which consequently results in measurable absorbances.

CSF NfL concentration, measured using a standard ELISA, is increased in several neurodegenerative diseases, FTD in particular. CSF NfL even distinguishes FTD variants; in a recent meta-analysis, higher NfL levels were noted in semantic PPA patients when compared with bvFTD and non-fluent PPA patients. Here, we replicate most of these findings using an immunoassay selective for oNfL. In fact, our data suggest that most of the NfL signal in earlier studies may have been derived from oNfL rather than NfL monomers.

*Figure 1* Oligomeric NfL (oNfL) concentration (pg/mL) measured with the homogeneous assay in different neurodegenerative diseases and healthy controls (A) and after SEC on in-house calibrator (B) or CSF (C). *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001, by one-way ANOVA test; bars represent 95% CIs; green dotted line, measured concentrations in collected fractions and dashed black line, absorbance at 280 nm. AD, Alzheimer's disease; ANOVA, analysis of variance; bvFTD, behavioural variant frontotemporal dementia; CSF, cerebrospinal fluid; nfvPPA, non-fluent variant primary progressive aphasia; SEC, size exclusion chromatography; svPPA, semantic variant primary progressive aphasia.
It is also important to emphasise that our assay may not detect all forms of oNfL, as oligomerisation might mask NfL21 epitopes in certain oligomeric species. However, from earlier studies, we are positive that this type of assay only detects oligomers of the target protein, and hence our results highlight this novel aspect of NfL as a biomarker. To examine the relative amount of oligomeric vs monomeric forms of NfL, as currently available assays cannot distinguish the two, an assay specific to monomeric NfL needs to be developed.

According to Budelier et al, NfL is present in the CSF as several different fragments, of which rod domain 2B fragments were identified and found to be correlating with results from the most widely used NfL ELISA (UmanDiagnostics). Our SEC results are in line with these findings, as in CSF, the peak fraction cannot correspond to full-length NfL, but rather oligomers of truncated NfL. Furthermore, we also observed that our calibrator eluted as a full-length dimer, confirming the oligomerised state of the protein. Previous studies, which also support our findings, state that the central part human NfL (detected by NfL21) has a strong propensity for self-assembly.

One question that remains to be answered is whether the oligomerisation occurs prior to or after release of the protein from the axon, and if oligomerisation is a part of the neurodegenerative process. We hypothesise that the protein is released as a dimer in both physiological and pathological conditions, given the strong propensity for oligomerisation of the coiled coil domain of NfL. To address this hypothesis, further research, including cell-based experiments and/or studies on acute axonal injury, is needed.

Nevertheless, the novel homogeneous ELISA described here, along with the SEC data, provide strong evidence of the presence of oNfL in CSF. In fact, the data suggest that most of NfL in calibrators and human CSF is a dimer; an important result if we are to standardise NfL assays by reference measurement procedures for which full characterisation of the target analyte is a prerequisite.

The graph shows a strong positive correlation between oNfL_21 (pg/mL) and oNfL_23 (pg/mL) with a correlation coefficient $r = 0.9913$ and a p-value $p < 0.0001$. The data points form a linear trend, indicating a consistent increase in oNfL_23 as oNfL_21 increases.
