#### Abstract

Background Previous studies have shown that those in lower socioeconomic positions (SEPs) generally have higher levels of behavioural non-communicable disease (NCD) risk factors. However, there are limited studies examining recent trends in inequalities. This study examined trends in socioeconomic inequalities in NCD behavioural risk factors and their co-occurrence in England from 2003-19. Methods This time-trend analysis of repeated cross-sectional data from the Health Survey for England examined the relative index of inequalities (RII) and slope index of inequalities (SII) in four NCD behavioural risk factors: smoking; drinking above recommended limits; insufficient fruit and vegetables consumption; and physical inactivity. Findings Prevalence of risk factors has reduced over time, however, this has not been consistent across SEPs. Absolute and relative inequalities increased for physical inactivity; relative inequalities also increased for smoking; for insufficient fruit and vegetable consumption, the trends in inequalities depended on SEPs measure. Those in lower SEPs experienced persistent socioeconomic inequalities and clustering of behavioural risk factors. In contrast, those in higher SEPs had higher prevalence of excessive alcohol consumption; this inequality widened over the study period. Interpretation Inequalities in smoking and physical inactivity are persisting or widening. The pattern of higher drinking in higher SEPs obscure the fact that the greatest burden of alcohol-related harm falls on lower SEPs. Policy attention is required to tackle increasing inequalities in smoking prevalence, low fruit and vegetable consumption and physical inactivity, and to reduce alcohol harm.

## Summary boxes

Section 1: What is already known on this topic
-Those in lower socio-economic positions (SEPs) have generally higher levels of behavioural non-communicable disease (NCD) risk factors than those in higher SEPs.

[^0]
#### Abstract

- Behavioural NCD risk factors tend to co-occur. -Whilst levels of some behavioural risk factors have been declining over the past decade it is unclear how this has occurred across SEPs and whether inequalities are widening or narrowing over time. Section 2: What this study adds - From 2003-2019, prevalence of smoking, excessive alcohol consumption, low fruit and vegetable consumption, and physical inactivity declined, however social-economic inequalities widened for smoking and physical inactivity. - On both relative and absolute scales, social-economic inequalities for low fruit and vegetable consumption narrowed across neighbourhood deprivation and income for women but widened across educational level for men, suggesting differential effects by sex and SEPs. -Those in lower SEPs had a higher prevalence of having two or more behavioural risk factors; this remained stable over the time-period.

Keywords Health inequalities, Healthcare disparities, Health policy, Public health, England

## Background

Non-communicable diseases (NCDs) cause an estimated 41 milliondeaths each year, $71 \%$ of all deaths globally [1]. Approximately 7.6 million people in the UK are estimated to be living with cardiovascular disease (CVD) [2] and 2.9 million with cancer [3]. This places a substantial demand on health services and society: prevention is crucial to reducing the morbidity and mortality associated with these diseases.
Four key modifiable behaviours are known to increase NCD risk, namely: tobacco use, unhealthy diet, physical inactivity and harmful use of alcohol [1]. There is also growing evidence suggesting that behavioural risk-factors often co-occur or cluster in individuals [4]. Where these behaviours co-occur, they are synergistic rather than additive (i.e., combination of risks may be greater than would be expected from adding up the individual risks alone) [4].
The risk of NCD mortality and morbidity is generally highest for those in the most deprived socioeconomic positions (SEPs) [5]. In addition, although the relationship is complex, generally more deprived groups have higher rates of behavioural risk factors [6]. For some populations, differing prevalence of behavioural riskfactors by SEPs has been found to explain most of the relationships between SEPs and NCD mortality. For example smoking and alcohol use explained much of the educational inequality in CVD in a Dutch cohort [7]. Further, although public health interventions have aimed to reduce the prevalence of behavioural riskfactors, some interventions are potentially less effective for the most deprived population groups [8, 9]. Perhaps as a consequence of this, changes in prevalence of some NCDs has been uneven. For example, an analysis of coronary heart disease mortality in England from 1982-2006 found steeper falls in mortality rates in the
least deprived areas so that relative inequality increased significantly, although absolute inequality declined [10].
Socioeconomic position is "an aggregate concept that includes both resource-based and prestige-based measures" [11]. Having a low SEP can mean being deprived of material resources, having limited opportunities, low social status, and exposure to an adverse social and physical environment at home and at work. Four measures of SEPs have often been used to examine the association with health: educational attainment, employment status, income level, and neighbourhood deprivation [12]. These measures each relate to a different aspect of an individual's SEP, and may be associated with NCD risk through different, although overlapping, pathways. For this reason, each measure may have differing associations with NCD risk. For example, in a study of a New Zealand population, CVD risk-factors were more strongly associated with area-based deprivation and income inequality than with occupation or education [13].
The aim of this study was to examine the national trends in socioeconomic inequalities in four behavioural NCD risk factors and their co-occurrence in England, using the nationally representative Health Survey for England (HSE) data. Additionally, this study examines whether there are differences depending on the SEPs measure used.

## Methods

## Survey design

This study used data collected in the HSE from 2003, when the ability to account for non-response weighting was introduced, to 2019 for the adult population (aged 16 years and over). HSE is a series of annual surveys of people living in private households in England. The detailed methodology of the survey has been described elsewhere [14]. In 2005, there was a boost sample of participants aged $65+$, but to retain national
representativeness and ensure comparable year on year analyses, only the core sample has been used. Interview weightings were applied in this study as all risk factors were derived from the interview stage of the survey. Household response rates to health examination surveys have steadily decreased over time in England and other countries [15].

## Patient and public involvement

Patients and the public were not involved in this secondary analysis. Public sector stakeholders are included in the HSE Steering Group that considers topics for inclusion each year.

## Data collection and definitions CVD risk factors measurement

Data on four behavioural risk factors were self-reported using standard questions [14] and were subsequently dichotomised as follows: (i) being a current cigarette smoker, (ii) drinking more than the UK previous recommended daily guidelines, based on the heaviest drinking day in the past week ( 4 units/d for men, 3 units/d for women), (iii) consuming fewer than the recommended five portions of fruit and vegetables per day and (iv) being physically inactive (spending < 30 min per week in mod-erate-to-vigorous intensity physical activity). Availability of each risk factor by survey year is presented in Table 1.

## Multiple risk factors

Physical inactivity was excluded from analyses of cooccurrence of multiple behavioural risk-factors (MRF) because its inclusion would have limited the analyses of multiple risk factors to only two time points when all four are available: 2008 and 2016.
The remaining three behavioural risk factors (excessive alcohol intake, smoking, and insufficient fruit \& vegetable consumption) were summed at the individual participant
level, with individuals classified as having $0-3$ behavioural risk-factors. Only the years where all three behavioural risk factors were collected have been included in the MRF analyses (2007-2011; 2013; 2015-2018).

## Socioeconomic positions

Individual and area-level factors can both contribute to health outcomes with complex relationship between them. Examining both types of measures provides a more comprehensive understanding of socioeconomic inequalities and could inform the development of targeted policies and interventions that address multiple levels of influence.
Socioeconomic position was measured using four indicators. Area deprivation related to the individual's home address, as measured by the index of multiple deprivation (IMD) 2015 (grouped into quintiles). The remaining three was collected via self-report at the main interview; highest educational attainment level (grouped into degree or equivalent, below degree, and no qualification); equivalised net disposable household income (adjusted for household composition and grouped into quintiles); and occupational status (grouped into managerial/professional, intermediate, manual and other).

## Statistics analyses

We maximised the sample by using all available cases, resulting in differing sample sizes across each variable, predominately driven by inconsistency in data collection over the study period (Table 1). The maximum sample size was for smoking ( $N=154,121$ ), followed by fruit \& vegetable consumption ( $N=127,936$ ), alcohol ( $N=108,200$ ), behavioural MRF $(N=84,646)$ and physical inactivity ( $N=65,178$ ).
Direct age standardisation was carried out for prevalence of each risk factor using the population estimates

Table 1 Behavioural risk factors and years of data available

| Risk factors | Details | Comparable years of data used | Total participants (aged $16+$ with no missing data) |
| :---: | :---: | :---: | :---: |
| Alcohol | Drinking more than sensible daily alcohol intake defined by consumption of $<=3$ units of alcohol for women and $<=4$ units of alcohol for men | 2007-2019 | 108,200 |
| Smoking | Current cigarette smoker | 2003-2019 | 154,121 |
| Fruit \& Vegetable | Consuming fewer than the recommended five portions of fruit and vegetables per day | 2003-2011, 2013, 2015-2018 | 127,936 |
| Physical inactivity | Being physically inactive by spending less than 30 min per week in moderate-to-vigorous intensity physical activity | 2003, 2004, 2006, 2008, 2012, 2016 | 65,178 |
| Behavioural Multiple risk factors | Combining Alcohol, Smoking, and Fruit \& Vegetables | 2007-2011, 2013, 2015-2018 | 84,646 |

for England for age groups 16-24, 25-34, 35-44, 45-54, $55-64,65-74$ and $75+$, derived from mid-year 2019.
The relative index of inequality (RII, measures relative change in inequality) and slope index of inequality (SII, measures absolute change in inequality) are the recommended measures to use when measuring change in inequality over time as they take into account the whole socioeconomic distribution and changes in population share of socioeconomic groups [16]. Reporting both measures is important to enable understanding of inequalities in NCD risk factors and to inform targeted policy interventions aimed at reducing both relative and absolute inequalities. Discrepancies in RII and SII trends would highlight the need to consider the underlying factors that are driving these inequalities.
To calculate RII and SII for each survey year, categories of each SEP at each survey were transformed into a summary measure referred to as a 'ridit' score, weighted to reflect the proportion of the sample at each category. Detailed description of how to calculate the ridit score have been described elsewhere [17]. The ridit scores were then included in linear probability models. A generalised linear model, with a logarithmic link function was used to estimate the RIIs and with an identity link function to estimate SIIs [16]. Due to well-documented convergence problems with log-binomial regressions, a log-Gaussian regression was used as an alternative as suggested in the literature [18]. The models were stratified by sex and adjusted for age. Missing data were excluded from analyses.
To estimate the trends in RII and SII over the survey years, the year variable was converted into a continuous variable in order to account for the different time periods between surveys, as recommended in the literature [19]. An interaction term between the derived ridit score for each socioeconomic variable and derived continuous year variable was included in the generalised linear models.
Analyses were conducted using Stata v16 and have taken into account the HSE's clustered, stratified design and non-response weighting using Stata's complex survey 'svy' prefix command. Strata with a single sampling unit were treated as certainty units.

## Results

## Descriptive analyses of the study population

Characteristics of the study population are shown in Table 2 ( $N=155,226$ adults aged $16+$ ). Between 2003 and 2019, the proportion of participants with a high education level (degree or equivalent) increased considerably from 19 to $30 \%$ for men and from 15 to $30 \%$ for women. There was a smaller increase in the proportion of participants with high occupational status (managerial or
professional, and intermediate) from 53 to $57 \%$ for men and from 51 to $59 \%$ for women. For most variables, missing data was non-existent or small $(<1-3 \%)$, with the exception of income where missing data ranged from $15 \%-24 \%$.

Table 3 provides a summary results, showing change in relative and absolute inequalities for the four behavioural NCD risk factors and their co-occurrence, by SEPs.

## Alcohol

Age-adjusted prevalence of participants drinking more than the current UK recommended daily guidelines decreased from $41 \%$ in 2007 to $33 \%$ in 2019 for men and from 31 to $27 \%$ for women (Table 4). Across both sexes, all socioeconomic groups showed a decrease in prevalence of excessive drinking over the study period, however those in the higher SEPs (i.e. least deprived, degree educated, managerial jobs, or top income) consistently had higher prevalence of excessive alcohol use than those in the lower SEPs. Time trends analysis showed that for men, deprivation inequalities in alcohol consumption increased significantly on both the relative scale ( $p=0.002$ ) and absolute scale ( $p=0.041$ ) whilst for women, although there was a widening of inequalities on both relative ( $p=0.021$ ) and absolute scales ( $p=0.080$ ), the widening was significant on the relative scale only. Occupational status inequalities increased for both sexes on a relative scale but remained stable on the absolute scale. Income inequalities increased on the absolute scale for men and on a relative scale for women. Education inequalities increased on the absolute scale for women.

## Smoking

Age-adjusted prevalence of current cigarette smoking decreased from $25 \%$ in 2003 to $18 \%$ in 2019 for men and from 24 to $15 \%$ for women (Table 5). Those in the lower SEPs consistently had a higher prevalence of smoking. Absolute inequalities in smoking remained stable for all measures of SEPs for both sexes during the study period. However, there was significant widening of relative inequalities by income (for both men, $p=0.007$ and women, $p=0.014$ ), by education (men, $p=0.023$ ) and occupational status (men, $p=0.031$ ). There was also widening of relative inequality by deprivation for women, but this did not reach statistical significance at the $5 \%$ level ( $p=0.069$ ).

## Fruit and vegetables

In 2003, age-adjusted prevalence of participants consuming fewer than the recommended five portions of fruit and vegetables daily was $78 \%$ for men and $74 \%$ for women. These improved slightly over the course of the study, but remained common at $75 \%$ for men and $70 \%$ for

Table 3 Summary results showing change in relative and absolute inequalities for four behavioural NCD risk factors and their co-occurrence

| Behavioural risk factors | Change relative and absolute inequalities by socioeconomic position indicators |  |
| :---: | :---: | :---: |
|  | Men | Women |
| Alcohol: drinking more than the UK recommended daily guidelines | ```Deprivation = RII and SII widened Education=NS Employment=R\|l widened Income=SIl widened``` | Deprivation = RII widened Education = SII widened Employment = RII widened Income=RII widened |
| Smoking: current cigarette smoker | Deprivation = NS <br> Education = RII widened <br> Employment = RII widened Income= RII widened | Deprivation = NS <br> Education=NS <br> Employment = NS <br> Income=RII widened |
| Fruit and vegetables: consuming fewer than the recommended five portions of fruit and vegetables per day | ```Deprivation = NS Education = RII and SII widened Employment = NS Income=NS``` | ```Deprivation=RII and SII narrowed Education=NS Employment = Sll narrowed Income=RII and SII narrowed``` |
| Physical inactivity: being physically inactive | Deprivation = RII and SII widened Education = RII and SII widened Employment = RII and SII widened Income = RII and SII widened | Deprivation = NS <br> Education=RII and SII widened <br> Employment = RII and SII widened Income = RII widened |
| Multiple risk factors: having two or more risk factors | ```Deprivation = NS Education=NS Employment=NS Income=NS``` | ```Deprivation = NS Education=NS Employment = NS Income= RII and SII widened``` |

"RII" Relative Index of Inequality (measure of relative change in inequality), "SII" Slope Index of Inequality (measure of absolute change in inequality), "NS"Not significant (No significant change in relative and absolute in inequalities)
women in 2018 (Table 6). Those in the lower SEPs were consistently more likely to have low fruit and vegetable consumption.
For women, there was narrowing of both relative ( $p=0.006$ ) and absolute inequalities $(p=0.003)$ by neighbourhood deprivation. Similarly for women, there were narrowing of both relative ( $p=0.004$ ) and absolute inequalities $(p=0.001)$ by income. Women also saw narrowing of occupational status inequalities on the absolute scale ( $p=0.043$ ).
Conversely for men, there was widening of both relative ( $p<0.001$ ) and absolute inequalities ( $p<0.001$ ) by education. All other measures of SEPs inequalities remained stable during the study period.

## Physical activity

Age-adjusted prevalence of physical inactivity decreased over the study period from $65 \%$ in 2003 to $57 \%$ in 2016 for men and from 76 to $66 \%$ for women (Table 7). In 2003, those in lower SEPs had a lower or similar prevalence of physical inactivity compared with those in the higher SEPs, as indicated by RII of below or near one and SII of below or near zero. However, by the end of the study, all RIIs and SIIs were above one (RII) and zero (SII), indicating that relative and absolute inequalities have widened. The p-values derived from the linear trend test showed that for men, there has been a significant
widening of both relative and absolute inequalities for all SEPs. For women, education inequalities and occupational status inequalities has widened on both the relative and absolute scale. Women also saw widening of relative inequality by income (Table 7).

## Multiple risk factors

In $2007,17 \%$ of the study population was estimated to have zero risk factors, $45 \%$ had one, $38 \%$ had two or three, and $8 \%$ had all three risk factors. By 2018, the proportion of the population with one risk factor had increased to $51 \%$ and there was improvement in those with two or three (decrease to $31 \%$ ), all three (decreased to $5 \%$ ) and zero (increased to $18 \%$ ) risk factors. Compared with women, men had higher prevalence of two or more risk factors ( $42 \%$ vs $33 \%$ in 2007 and $35 \%$ vs $26 \%$ in 2018) and lower prevalence of zero ( $15 \%$ vs $21 \%$ in 2018) or one risk factor ( $49 \%$ vs $53 \%$ in 2018).

Overall, after adjusting for age, the proportion of the population with two or more risk factors decreased from $41 \%$ in 2007 to $35 \%$ in 2018 for men and from 33 to $26 \%$ for women (Table 8). For women, there was narrowing of both relative ( $p=0.009$ ) and absolute inequalities $(p=0.025)$ by income. All other measures of SEPs inequalities remained stable during the study period for both men and women.
Table 4 Alcohol: Sex stratified Age-adjusted Prevalence of men and women drinking more than the UK recommended daily guidelines and age-adjusted RII and SII by deprivation, education, occupation and income (prevalence weighted for non-responses \& cluster sampling). RII=Relative Index of Inequality (measure of relative change in inequality). SII = Slope Index of Inequality (measure of absolute change in inequality)

Table 6 Fruit \& Veg: Sex stratified Age-adjusted Prevalence of men and women consuming fewer than the recommended five portions of fruit and vegetables per day and ageadjusted RII and SII by deprivation, education, occupation and income (prevalence weighted for non-responses \& cluster sampling). RII = Relative Index of Inequality (measure of
relative change in inequality). SII = Slope Index of Inequality (measure of absolute change in inequality)

## Discussion

Prevalence of all four behavioural risk-factors reduced over the course of the study period, although prevalence of insufficient fruit and vegetable consumption remained high. In terms of patterns by SEPs, for smoking and inadequate fruit and vegetable consumption, those in lower SEPs consistently had higher prevalence of the risk factors; for physical inactivity, this also became true by the end of the study period. Relative and absolute inequality grew over the period for physical inactivity and relative inequality but not absolute inequality grew for smoking. For fruit and vegetable consumption, the inequalities depended on SEPs measure: both absolute and relative inequality narrowed for women by neighbourhood deprivation and income, but for men both relative and absolute inequality widened by education. In contrast to other risk-factors, those in higher SEPs had higher prevalence of alcohol consumption above daily limits than those in the lower SEPs; this inequality was generally widening. In terms of co-occurrence of risk-factors, the picture was improving at a whole population level, with the prevalence of two or more risk-factors decreasing and the prevalence of no risk-factors increasing. However, those in lower SEPs had higher prevalence of two or more riskfactors and this inequality did not change significantly for any measure of SEPs, except for inequalities by income for women.
The inequalities in physical inactivity are concerning. Studies published around the start of time period noted that those with higher SEPs completed more leisure time physical activity than those with lower SEPs [20], with occupational physical activity higher in groups with lower SEPs. Examining total physical activity may have obscured differences in physical activity for leisure and non-leisure by SEPs. Future research should examine whether reductions in occupational and travel physical
activity, particularly for low SEPs, have led to widening inequalities in total physical activity. A study of OECD countries using data collected up to 2014 noted that in England, Australia, Korea, Spain and the US, those with higher educational status had lower prevalence of insufficient physical activity, but the opposite was true in Chile and Mexico [21]. This suggests there may be a transition as countries have increasingly mechanised work and travel, in which risk of physical inactivity for those with low SEPs increases to a greater extent than for those with high SEPs. Following the COVID-19 pandemic, it is unlikely that England will ever return to having an economy in which occupational physical activity is accrued to any great extent by a large proportion of the population. Therefore, a focus on active travel and leisure time physical activity is needed. Increasing affordability of these may support increased physical activity for those with lower SEPs. Accessibility also needs to be considered, with neighbourhoods requiring investment to support active travel and recreation.
The persisting and/or widening inequalities in smoking behaviour requires attention. Tobacco use significantly increases the probability of dying prematurely as well as decreasing quality of life. Smoking has previously been identified as contributing the most to social inequalities in health outcomes [22]. Despite a number of population level policy interventions (ban on smoking in enclosed public spaces in 2007, ban on smoking in cars with people under 18 in 2015 and plain packaging in 2017), inequalities in smoking persist and have continued to widened for some of the SEPs, although tobacco use has decreased overall. Studies in other countries have similar persisting or widening socioeconomic inequalities in smoking behaviour [23, 24]. The most recent review to examine the inequality in impact of population tobacco control measures suggested that price increases and targeted
Table 8 Multiple Risk Factors: Sex stratified Age-adjusted Prevalence of men and women with two or more risk factors and age-adjusted RII and SIl by deprivation, education, occupation and income (prevalence weighted for non-responses \& cluster sampling). RII=Relative Index of Inequality (measure of relative change in inequality). SII=Slope Index of Inequality (measure of absolute change in inequality)

population-level cessation support were the only interventions where there is consistent evidence of a greater effect among low SEPs smokers [25]. Re-visiting affordability of tobacco in England, and ensuring local authorities are able to maintain effective and accessible cessation services may support reducing inequalities in prevalence of tobacco use in the future. Social interventions may also be needed, as smoking behaviour spreads through social influences which may maintain higher smoking rates within social networks which share low SEP [26].
For alcohol, the pattern of higher levels of drinking in higher SEPs belies the fact that the greatest burden of alcohol-related harm falls on populations with lower SEPs [27]. Alcohol-related hospital admissions have increased over the time period, and this increase was more concentrated in deprived areas reflecting this paradox [28]. It is worth noting that we examined whether participants consumed more than a daily threshold of 3 units for women, 4 for men; but patterns of drinking more than a higher daily threshold such as heavy episodic drinking, or a weekly threshold might highlight other inequalities. There is evidence to suggest that low socioeconomic groups are more likely to drink at extreme levels, including four times the threshold [29], which this study did not examine. In a study of 17 European countries from 1980-2010, there was greater alcohol related mortality in those with lower educational status in all countries studied [30]. The study also found that relative educational inequality in alcohol related mortality increased over time in most countries and the absolute educational inequality in alcohol related harm increase markedly in Hungary, Lithuania, Estonia, Finland and Denmark, while staying stable in France, Switzerland, Spain and Italy [30].
Finally, the fruit and vegetable analysis clearly demonstrates that the measure of SEPs matters. Both relative and absolute inequalities are narrowing by neighbourhood deprivation and by income for women. Meanwhile, relative and absolute inequalities by education status are widening for men. Potentially, understanding which indicators of SEPs are associated with widening inequalities could suggest potential policy targets; in this case suggesting that a focus on diet for groups (particularly men) with poor education may be important. Meanwhile further narrowing of inequalities by neighbourhood deprivation and income might be supported by increasing access and affordability of fruit and vegetables. A study of the Scottish diet between 2001 and 2007 found very little change in absolute or relative inequalities in intakes of food or nutrients [31]. A study of OECD countries, analysing data collected between 2003 and 2013 or the closest available years, found that the largest relative and absolute educational inequalities were in Canada,

England, Mexico and in Korean men and that trends in relative educational inequalities had increased or remained stable, while absolute educational inequalities had reduced or remained stable for men, while increasing for women (in contrast to our findings). The same study found that relative socio-economic inequalities (undefined in the report) had increased for men and decreased for women and absolute socio-economic inequalities had risen for both men and women [21]. None of these studies examined the same time period as our study, which may explain the differences in findings.

The strengths of this study are that we used robust, standardised national datasets with indicators that are comparable year on year and applied robust weighting for non-response. We were able to examine a range of SEPs measures and compare and contrast our findings. However, we used IMD 2015 for the whole study period, which may not be an accurate marker of deprivation across all the study years, and a around a fifth of the population had missing data for income which might have introduced bias in our findings.

Statistically, generalised linear models (log-Binomial regression) with logarithmic link function would have been the most appropriate method for our analyses, however the models repeatedly failed to converge in Stata when RII was close to 1 . This is a known problem with log-Binomial regressions. We used generalised linear models (log-Gaussian regression) as suggested in the literature to address this issue [18].
Finally, we note that there are many measures and indicators that could have been chosen for each of the behavioural risk-factors studied, some of which are discussed above. For example, there are many dietary behaviours that are important for health, other than fruit and vegetable consumption and the threshold for examining the risk-behaviour could have been set differently (e.g. for physical inactivity we could have used < 150 min MVPA per week; for fruit and vegetable consumption we could have used < 1 portion per day). Furthermore the lack of consistent years data particularly on physical activity prevented us from exploring the co-occurrence of more than three risk-factors over the period.
Further research examining the trends in inequalities in prevalence of behavioural risk-factors for NCDs in other countries, which could be compared with our findings, could give additional insight into how the wider sociopolitical environment of England (and other countries) might be affecting inequalities in risk behaviours.

## Acknowledgements

We thank the survey participants, the NatCen fieldstaff, and colleagues at NatCen Social Research for their contributions to the successful collection and archiving of HSE data.
