12

13 **Abstract**

14 **Purpose of review**

15 To discuss recent evidence on the influence of complementary feeding (CF) timing, content and
16 feeding methods on childhood obesity risk.

17 **Recent findings**

18 The evidence-base is limited by heterogeneity, risk of bias and the predominance of observational
19 studies. The content of the diet and feeding practices are more influential than timing for obesity
20 risk. There is limited evidence that CF introduction before 4 months may be associated with
21 increased risk. Intake of animal protein, particularly dairy protein, may contribute to rapid weight
22 gain; protein from infant/follow-on formula shows the most robust association with later obesity
23 risk. Evidence linking sugar intake to obesity risk is limited, but intake should be as low as possible
24 given there is no nutritional requirement. Responsive feeding (RF) practices may promote
25 appropriate infant growth and reduce risk. The effect of baby-led weaning is inconclusive.

26 **Summary**

27 Recent evidence supports current recommendations to avoid high protein intakes, especially from
28 infant/follow-on formula, for infants in HIC; and to promote responsive feeding practices for all
29 infants. Studies in LMIC are required to define optimal CF practices given increasing rates of child
30 obesity alongside double-burden malnutrition.

31 **Key words (3-5):** Complementary feeding, obesity, timing, content, feeding method

32

33

34

35 **Key points:**

- 36
- During the complementary feeding (CF) period infants are growing and developing rapidly,
37 have high nutrient requirements and are exposed to new foods, flavours and feeding
38 experiences which can influence infant growth trajectory and potentially influence later
39 obesity risk
 - The content of the CF diet and feeding practices are more influential than timing for
41 obesity risk.
 - Intake of animal protein, particularly dairy protein, may contribute to rapid weight gain;
43 protein from infant/follow-on formula shows the most robust association with later
44 obesity risk.
 - Evidence linking sugar intake to obesity risk is limited, but intake should be as low as
46 possible given there is no nutritional requirement.
 - Responsive feeding (RF) practices may promote appropriate infant growth and reduce
48 risk. The effect of baby-led weaning is inconclusive.
- 49
- 50

51 **Introduction**

52 Starting from the middle of the first year of life, breast milk alone can no longer meet infant nutritional
53 requirements and additional 'complementary' foods are needed to support their rapid growth and
54 development during complementary feeding (CF). CF practices, encompassing the timing, content and
55 method of feeding, can influence infant growth trajectory and result in both under and overnutrition,
56 depending on both infant and environmental factors. Child obesity has long been recognised as a
57 problem in high income countries (HIC) but it is also increasing rapidly in low- and middle-income
58 countries (LMIC), with many experiencing so-called double burden malnutrition. Alongside this, CF
59 practices in many LMIC are transitioning from predominantly home-prepared foods to commercial
60 products which may be high in energy, fat, salt or added sugar. These changes are considered as key
61 factors contributing to child overweight/obesity [1]. Furthermore, the provision of ultra-processed
62 foods in children may result in adverse metabolic outcomes according to a recent systematic review
63 (SR) [2]. Research on CF is challenging for several reasons, and study results can be difficult to interpret
64 and compare. Different definitions of CF are used, and it is not always possible to distinguish effects
65 of milk feeding from that of other foods. Parents often have strong preferences and may be reluctant
66 to participate in trials requiring different practices. Hence, most research is observational with high
67 potential for confounding by factors related both to CF and to the risk of later outcomes including
68 obesity. Accurately recording CF practices is challenging, with some studies using retrospective
69 maternal recall. Finally, the assessment of nutritional intake or dietary patterns is difficult, considering
70 the need to maximise data quality whilst minimising parental burden.

71 In this review we provide an update on the evidence that CF practices may influence the risk of
72 overweight/ obesity, considering timing, content and method of feeding and prioritising data from
73 SR with or without meta-analysis (MA).

74

75 **Timing of complementary feeding introduction**

76 Two SR and MA [3, 4] concluded there is no evidence that introducing CF before 6 months of age (M)
77 influences weight, BMI or the risk of overweight/obesity. The SR by English et al [5] reported limited
78 evidence that introducing CF or beverages before 4M may be associated with higher risk; interestingly,
79 these studies were considered to be at high risk of bias in the EFSA review [3].

80 Six recent observational studies (not included in the reviews above) examined associations between
81 infant feeding practices and either weight or BMI at a single time point or BMI trajectories (see Table
82 1 for details). All adjusted for a range of potentially important confounders. Two reported no
83 association between CF timing and later weight status [6, 7], whereas four reported greater adiposity
84 outcomes with CF introduction before 4M [8, 9] (one significant only in non-breast-fed infants [9]) or
85 6M [10, 11]. In common with most previous studies, none adjusted for infant or child nutrient intake,
86 physical activity, sedentary behavior, or sleep patterns – all factors known to influence weight
87 trajectory and overweight/obesity risk.

88 Differding et al [12] examined the role of the gut microbiome as a potential mediator between infant
89 feeding practices and later BMI using data from a Canadian cohort with BMI and stool microbiota
90 assessed at age 5 years. Their findings suggested that the effect of early CF introduction on gut
91 microbiota composition and BMI in childhood may depend on whether the infant is breast-fed or
92 formula-fed at the time. The same authors also reported altered gut microbiota with significantly
93 higher Shannon diversity and higher butyric acid concentrations in the stool at 3 and 12M in infants
94 with early ($\leq 3M$) versus late ($> 3M$) CF introduction [13]. However, the significance of the findings is
95 currently unclear in terms of future metabolic or immune outcomes. In a longitudinal analysis of infant
96 stool samples, Galazzo et al [14] reported that from 13 weeks onward, diet became the most
97 important determinant of microbiota composition; however changes were associated with cessation
98 of breastfeeding rather than solid food introduction.

99

100 **Complementary food content and dietary patterns**

101 *Energy and fat*

102 SRs have concluded that there is no convincing evidence of a relationship between the intake of
103 energy, fat (including different types of fat such as long-chain fatty acids) during CF and
104 overweight/obesity risk [5, 15-16]. In contrast, a SR/MA using data from LMIC suggested that lipid-
105 based nutrient supplements (LNS) provided with CF are effective in improving ponderal and linear
106 growth of infants and young children (6-23M) compared to no intervention [17]. Although one cluster-
107 randomised trial showed no difference in fatness among infants receiving LNS during the CF period
108 versus controls, long-term follow-up is needed to ensure favourable outcomes at older ages [18].

109 *Protein: Amount and Source*

110 Evidence suggests that higher protein consumption in early life is an important risk factor for increased
111 child overweight/obesity risk and body fatness [15,19]. The most recent review reported a probable
112 positive association between total protein intake in early life ($\leq 18M$) and higher BMI later in childhood
113 (BMI increase of 0.06 (95% CI 0.03, 0.1) kg/m² per 1% increment of energy from protein) [20]. Limited
114 evidence also suggested an effect of protein intake on higher overweight/obesity risk [20]. Expert
115 groups have recommended avoiding high protein intakes during CF, including limiting protein intake
116 to $\leq 15\%$ of total energy to reduce the risk of childhood overweight/obesity [21].

117 There is increasing focus on the influence of protein source. Currently, robust evidence only supports
118 a causal effect of high protein intake from infant and follow-on formula on rapid weight gain and child
119 overweight/obesity [15, 16]. Although the latest SR reported that protein from animal source foods
120 (ASF) was more likely to be positively associated with higher weight and BMI/BMI z-score (BMIZ), it
121 was unclear whether protein from dairy and non-dairy ASF had similar impact [20]. A previous SR
122 concluded that there was moderate evidence that consuming different amounts of meat does not
123 influence growth, body size or body composition in later life, with insufficient evidence to make a
124 conclusion regarding child overweight/obesity [5].

125 A recent prospective cohort study in Thailand (a MIC) reported that protein from formula and cow's
126 milk had greater impact on infant weight gain during the CF period than protein from non-dairy ASF,
127 while growth parameters were not associated with plant-based protein intake [22]. A SR/ MA also
128 reported no effect of plant-based diets during CF on weight gain or obesity risk, although these diets
129 may increase the risk of micronutrient insufficiency/deficiency and growth faltering [23].

130 Current evidence suggests that animal protein may increase plasma amino acid concentrations,
131 especially branch-chained amino acids (BCAA), which may enhance insulin and insulin-like growth
132 hormone (IGF-1) secretion resulting in greater weight gain and potentially higher overweight/obesity
133 risk [20]. The observed positive association between protein intake and insulin, IGF-1 and IGFBP-3
134 concentrations in the Thai cohort study was explained by protein from formula and cow's milk;
135 consumption of protein from non-dairy ASF or plant-based foods had no significant effect on these
136 hormones [22].

137 *Sugar and sugar-sweetened beverages (SSB)*

138 A SR [5] concluded there was limited evidence that SSB consumption during the CF period is associated
139 with increased obesity risk in childhood but not with growth, size or adiposity. There was also limited
140 evidence showing a positive association between juice intake and infant and child anthropometry. A
141 more recent SR/MA concluded there was low certainty evidence that consumption of SSB and
142 unhealthy foods in childhood (≤ 10.9 years) may increase BMI/BMIZ, body fatness, or odds of child
143 overweight/obesity. However, firm conclusions could not be made regarding sugar intake during the
144 CF period due to inconsistent findings, limited number of studies and serious risk of bias [24].
145 Nevertheless, one study suggested that frequent SSB consumption during the CF period (≥ 3 times a
146 week) was associated with greater odds of obesity at 6 years compared to infants without SSB intake
147 [24]. Notably, this SR/MA did not include studies from LIC and only 11.5% of studies were from MIC,
148 whereas a previous survey reported high intake of SSB and sugary snacks among children (12-23M) in
149 18 LMIC [25].

150 Although sugar intake should be as low as possible during the CF period, in practice intakes are often
151 high, and there is concern about the high sugar content of some commercial CFs, especially finger-
152 foods. A survey conducted in 10 European countries reported that approximately one-third of the
153 energy in commercial CF comes from sugar and, for most product categories, energy from sugar is
154 higher than 10%, exceeding WHO recommendations [26].

155 *Dietary patterns*

156 Some studies have used 'dietary patterns' as an alternative way to reflect food consumption. Such
157 methods typically identify patterns regarded as more 'health-conscious' (e.g., higher intake of fruits,
158 vegetables, whole grains, and home-cooked meat/fish) and those including more refined
159 carbohydrate foods, commercial or processed foods. A recent review concluded there was some
160 evidence that more 'health-conscious' CF dietary patterns may contribute to more appropriate weight
161 gain and favourable body composition in infants and young children which might prevent
162 overweight/obesity in later life [27]. However, effects were modest, and few studies measured body
163 composition. Previous reviews focusing specifically on fruit and vegetable intake during CF did not
164 demonstrate a preventive effect on child overweight/obesity [15, 28-29]. Evidence on the impact of
165 dietary patterns is thus limited and further well-designed research is needed.

166

167 **Method of complementary feeding**

168 Research has considered the role of responsive feeding and parenting practices, and the use of baby-
169 led weaning (BLW) versus traditional spoon-feeding during CF.

170 *Responsive feeding and parenting*

171 Responsive practices – including educating parents to respond to infant hunger and satiety cues and
172 avoiding the use of food to comfort or reward – were investigated in three previous RCTs with positive
173 short-term effects on infant growth and lower BMI, although this was not maintained at 3-5 years

174 [30]. Recently Savage et al [31] reported data from the INSIGHT trial suggesting that intervention
175 effects may spill-over to second-born infants, despite no reinforcement during the subsequent
176 pregnancy. Firstborn and second-born children whose parents received the intervention with the first
177 child had BMI that was 0.44 kg/m² (95% -0.82 to -0.06) and 0.36 kg/m² (95% CI -0.75 to 0.03) lower
178 than controls. However, infants were only measured up to 12M and longer-term follow-up is
179 important given the lack of persistence of intervention effects in the main trial.

180 A more recent RCT investigated the effects of repeated vegetable exposure, sensitive feeding or a
181 combination of both in 246 healthy Dutch infants recruited at 4-6M and evaluated at 18 and 24M [29].
182 Interventions lasted until 16 months and had no impact on the primary outcomes – vegetable
183 acceptance and energy intake. The proportion of children with overweight was significantly lower in
184 the combined intervention group compared to the vegetable group at 18M (2% v 16%) and the control
185 group at 24M (7% v 20%). However, the authors suggest this finding should be interpreted with
186 caution due to the small number of infants with overweight and non-significant effects on continuous
187 BMIZ measures.

188 Other studies have investigated associations between infant appetite, parenting styles and infant
189 growth. In Mexican infants from a prospective birth cohort, 'pressuring to finish' and 'pressuring to
190 eat cereal' constructs from the Infant Feeding Styles Questionnaire were associated with lower
191 weight-for-length and BMIZ at 6M (n=263) with a similar although non-significant effect at 9M (n=234)
192 [32]. However, the possibility of reverse causality cannot be excluded, where parents may have
193 pressured the infant to eat because they were concerned about slow growth. Shriver et al [33]
194 investigated interactions between infant appetite traits and restrictive and pressuring parental styles
195 on infant weight gain in a longitudinal cohort of 159 mother-infant pairs studied at around 2M and
196 between 6-11M. They concluded that, for infants with a large appetite, some level of restrictive
197 feeding may be beneficial for preventing excessive weight gain while pressurising may exacerbate the
198 positive association between faster eating and rapid weight gain.

199 *Baby-led weaning*

200 The BLW approach has been suggested to allow greater self-regulation by the infant and promote
201 better appetite control which could result in lower overweight/obesity risk. However, the lack of a
202 consistent definition of BLW makes it difficult to compare studies. Furthermore, most evidence comes
203 from observational studies, which is problematic given that characteristics of parents using BLW differ
204 from those favouring a more traditional spoon-feeding approach, and these same factors may also be
205 associated with obesity risk. A randomised trial using a modified BLW intervention (BLISS) in New
206 Zealand reported no effect on infant weight or adiposity at 24M [30].

207 Two recent SR investigated effects of BLW on infant growth and appetite outcomes. Boswell [34]
208 included 29 studies (1 RCT) in a narrative review restricted to HIC and using a single database. The
209 authors concluded that benefits of BLW included lower food fussiness, higher food enjoyment, lower
210 food responsiveness and higher satiety responsiveness – a profile which might be expected to confer
211 reduced obesity risk. However, few studies robustly examined the relationship between BLW and
212 obesity risk. Martinon-Torres et al [35] searched 4 databases and 8 studies were included, including
213 two RCTs. Results were inconclusive. All studies were considered to be at moderate to high risk of bias
214 and only one RCT was pre-registered.

215 In a third SR/MA, Bergamini et al [30] investigated effects of a wider range of CF practices. There was
216 no evidence that BLW approaches had any benefit for infant weight/length gain nor a preventive effect
217 on future overweight/obesity. However, responsive feeding practices were found to result in
218 adequate weight gain and lower incidence of overweight/obesity during the first two years of life.
219 Conversely, non-responsive feeding styles, namely restrictive and coercive practices, had a negative
220 effect, favouring excess weight and lower weight respectively.

221 **Conclusions**

222 Current evidence suggests that the content of the CF diet and the method of feeding are more
223 influential than timing with respect to obesity risk. High protein intake from formula during the CF
224 period can promote rapid weight gain and may increase the risk. Evidence for a specific effect of
225 protein intake from other foods is less robust, but some data suggest that intake of animal protein,
226 especially from dairy sources, has a greater effect on weight gain than that from non-dairy ASF or
227 plant-based foods. BCAA may be a possible mechanism linking animal protein intake with increased
228 secretion of growth-promoting hormones and faster weight gain. However, further research is
229 required to assess longer-term effects of specific protein sources, as well as investigating underlying
230 mechanisms.

231 Evidence linking sugar intake during CF with later weight or obesity risk remains limited in quantity
232 and quality. However, considering there is no nutritional requirement for sugar, which provides empty
233 calories and is bad for dental health, intake should be minimised and efforts made to lower the sugar
234 content of commercial weaning foods as well as advising parents to limit sugar in home-prepared
235 foods.

236 The evidence for a beneficial effect of responsive feeding or parenting practices on infant weight and
237 overweight/obesity risk appears greater than that for BLW, although the latter may form part of
238 responsive feeding by increasing infant control during feeding. This supports the inclusion of advice
239 on responsive parenting in current infant feeding recommendations.

240 In general, recent studies suffer from the same methodological limitations as older studies, and some
241 of these are difficult to address in practice. A further significant limitation of the current evidence-
242 base is that most studies were conducted in high-income, western countries. Their findings may not
243 be generalisable to other settings and high-quality research from LMIC where double burden of
244 malnutrition is also prevalent are particularly required.
