Wearables integrating movement sonification can support body-perception changes and relatedly physical activity; yet, we lack design principles for such sonifications. Through two mixed-methods studies, we investigate sound pitch and movement direction interaction effects on self-perception during squats exercises. We measured effects on body-perception, affective quality of the experience, actual and perceived movement, and compared them to two control conditions: no-sound and vibrotactile feedback. Results show that regardless of movement direction, ascending pitch enhances several body feelings and overall experience quality, while descending pitch increases movement acceleration. These effects were moderated by exercise physical demand. Sound and vibrotactile feedback enhanced flexibility and strength feelings respectively and contributed to exercise completion in different ways. Sound was perceived as an internal-to-body force while vibrotactile feedback as an external-to-body force. Feedback effects were stronger in people with lower fitness levels. We discuss results in terms of malleability of body-perceptions and highlight opportunities to support demanding physical activity through wearable devices.

CCS Concepts: • **Human-centered computing** → **Human computer interaction (HCI)**; **Interaction design process and methods**; **Systems and tools for interaction design**; • **Applied computing** → **Sound and music computing**; **Psychology**.

Additional Key Words and Phrases: Embodied Interaction, Sports/Exercise, Wearable Computers

1 INTRODUCTION

Low physical activity is a global public health problem contributing to almost 3.2 million deaths each year [72]. To combat this, various activity tracking devices and applications (e.g., Fitbit, GoogleFit) have been developed, primarily

based on personal informatics principles [76, 108] and implementations of behaviour change techniques [40]. However, insights obtained by self-tracking can be insufficient to facilitate physical activity [108] and research suggests that factors associated with body perception should also be taken into consideration [4, 54, 57]. In particular, recent work has shown how sound feedback associated with body movement (sonification) can affect people's body perceptions (e.g., altering footstep sounds [91]), and in turn their emotional state and movement behaviour [57, 95]. However, we lack design principles for such sonification in relation to body transformation experiences (i.e., changes in body perception) and physical activity.

Recent work indicates clear opportunities for sonification-based technologies using artificial sounds changing in pitch for altering body-perceptions and facilitating movement. A first study using such sounds showed that an ascending pitch sound triggered by the action of pulling one's finger, can make one's finger feel longer [67, 97]. Such an "auditory Pinocchio" illusion could result from associating sound pitch changes with changes in height, size and motion along the vertical plane [22, 58]. Building on this, in a recent study we investigated the effect of pairing ascending and descending pitch sounds with an upward body movement (arm raise) on the perceived body position (i.e., proprioceptive awareness) and movement [55]. The investigation comprised three quantitative experiments with 25 participants in the first two studies and 20 in the final one. Participants synchronised an arm raise with sounds changing pitch in simple tones (Experiment 1), rich musical sounds (Experiment 2) and within different frequency ranges (Experiment 3), while their movement, body-representations and feelings were recorded. Results showed that ascending pitch sound induces a sense of lightness and ease, accelerating movement and motivating exercise completion [55]. Conversely, descending pitch creates a sense of heaviness and slowness. But, *it remains to be seen if these effects extend to exercises requiring larger effort* [55]. High intensity exercises may lead individuals to focus more on overwhelming physiological sensations rather than on the sound [41]. In this paper, we address three gaps by exploring, quantitatively and qualitatively, the effect of sound on a strength exercise on inactive and quasi inactive people. These gaps are summarized here:

Firstly, few studies have focused on strength exercises but they were either not focused on altering body perception and capabilities [69] or explored natural sound alterations, like footstep sounds, rather than augmented movement sonification [91, 95]. A more related study examining the effects of various metaphorical sounds [57] demonstrated positive effects of sounds changing in pitch in a small sample of inactive participants performing strength exercises (squats and steps-up). However, the study had a small sample size (5 inactive people vs 7 highly active people) and employed only qualitative methods, lacking measures of behavioral effects. While such small qualitative studies provide some initial understanding of how sound impacts body- perception in strength exercises, quantitative approaches are necessary to understand the effects of specific sonification qualities.

105 Secondly, studies on sound and body size perception (e.g., finger length) [97] overlook interactions between sonifica-
106 tion direction and movement direction. Further, interaction between the movement direction (i.e., up and down), and
107 the perceived sound pitch (i.e., ascending and descending) is not studied in the physical exercise context. This gap is
108 particularly relevant in strength exercises, where downward and upward movements may pose different challenges.
109 While upward movement in exercises (e.g., arm raise) has been studied (e.g., [55]), no single study has explored the effects
110 of the descending pitch sound on downward movement. Whether the potential effects mirror those of upward movement
111 is not obvious. While congruence between movement direction and sound direction may facilitate a demanding exercise,
112 it is uncertain how sound direction may produce different changes in body perceptions and how such perceptions
113 influence movement execution.
114

116 Finally, the third gap is methodological: studies focusing on the effect of sound on perceived body size and movement
117 capabilities contrast sound feedback with a control sound condition or no feedback (no-sound condition). We propose
118 adding another sensory modality as a control condition, may help to better understand the effect of sound through a
119 contrasting experience of feedback. While one quantitative study [11] explored the combination of sound with another
120 modality (smell), it focused on the effect of smell on body- perception, not movement representation. While both haptic
121 and visual feedback have been studied for their facilitating effect in physical activity and movement trajectory (see
122 related works in other contexts [12, 30, 81]), to our knowledge, no studies yet investigate the effects of sounds changing
123 in pitch on body perception alongside those sensory feedbacks in our application context. Indeed, existing studies
124 on physical activity primarily use feedback from multiple modalities mainly to compare their effects on adhering to
125 movement trajectory and target only, and not to alter people’s perception of their own body and movement.
126

128 To address the identified gaps, we conducted two studies. First, a mixed methods remote study (n=22) focused
129 on participants performing squat exercises (Experiment 1), where ascent and descent were sonified by ascending or
130 descending musical sounds (Figure 1). Squats are a physically demanding exercise involving two effortful directional
131 phases of movement, upwards and downwards, unlike the arm raise in [55], where only the upward movement is
132 effortful. We analysed self-report and sensor data to understand how sound direction affects perception of movement
133 and movement characteristics. The second study (Experiment 2) aimed for a deeper understanding of the effect of sound
134 on movement perception and facilitation, and perceptions across the whole body through another mixed methods
135 study (n=21). Squats exercises were accompanied by movement sonification, with two control conditions: (i) no sensory
136 feedback, (ii) haptic feedback. The two conditions aimed to trigger comparative reflections in participants on the
137 different experiences. Haptic feedback, like sound, doesn’t interfere with movement, as people do not need to visually
138 fixate on it, and it has been shown to reduce perceived workload and improve performance [13, 38]. Further, haptics is
139 a primary sense developed in infancy [64], increasingly used in user interfaces to convey rich information [9, 10, 29]. It
140 is widely shown in neuroscience research to contribute to people’s perception of their own body and action [5, 105]
141 and used in the context of physical activity for movement guidance [84] (see [82] for an overview). The use of haptics
142 is also highlighted in the HCI domain of soma design (e.g., work on the *Soma Corset* [47] and the *Breathing Wings*
143 [106]). Our focus in Experiment 2 was on participants with low or moderate levels of physical activity because they
144 may experience larger effects of the feedback on their body and movement [56]. This paper makes three contributions
145 that are discussed next:
146

151 First, we show that directional movement sonification can facilitate a vertical strength exercise by influencing body-
152 perception and overall experience quality (in this paper this term encompasses affective experience and other aspects
153 related to people’s body and movement as an outcome of the sound effects). However, the psychological mechanisms
154 triggered depend on sound direction. The upward sonification triggers feelings of being lighter, less tired and more
155

157 capable, while the downward sonification triggers feelings of being heavier and of greater movement acceleration,
158 independently of the movement direction. This extends previous literature [55] by suggesting that movement sonification
159 with sounds changing in pitch can facilitate strength exercises, not just simple movements. Moreover, departing from
160 the constancy effect observed in [97], this study shows that the congruence between the movement direction and sound
161 amplifies related effects in strength exercises. For example, feeling heavier in an upward movement could be perceived
162 as negative but the same feeling may be enjoyed and facilitate a downward movement. Thus, ascending and descending
163 sounds can generate different body changes and changes in experience quality to support movement in different ways.
164

165
166 Second, our study shows that both sound and vibration feedback are linked to rewards during movement and to the
167 sensation of force being exerted by the feedback guiding and helping to perform the squats; it is noteworthy that sound
168 feedback is regarded as an internalized force while vibration feedback as an externalized force.

169
170 Finally, our study highlights the potential variation of effects according to the person's fitness level, with stronger
171 effects in people with lower fitness. This presents new opportunities in supporting people who struggle the most with
172 physical activity and contributes to the literature on factors that we identified as interacting with how body perception
173 is built, adding physical activity level to the already identified personal values [95]. We discuss design opportunities
174 to enhance body-perception through wearable devices for supporting physical activity in the context of a strength
175 workout that are made possible in light of our findings.
176

177 178 2 RELATED WORK

179 2.1 Auditory-induced Changes in Body Representation

181 We interact with, think about, and perceive the world around us through our bodily senses [5, 32, 91]. The multisensory
182 feedback generated by our actions is continuously used by our brains to adapt our mental body representations [14, 59].
183 Altering body-produced auditory feedback has been shown to be a particularly powerful way of changing how we
184 perceive our bodies and in turn act in the world (for a review see [87]). For instance, artificially lengthening the time
185 taken to hear an object fall on the ground after being dropped from one's hand changes the internal estimates of the
186 body height so people report feeling taller and behave as if their legs were longer [91]. Moreover, manipulating the
187 auditory distance of tapping sounds when tapping one's hand on a surface can alter the mental representation of
188 one's arm length, whereby increasing the auditory distance increases the perceived length [94, 96, 99]. This mental
189 representation of a longer arm in turn affects the arm reaching movement in a way that is consistent with having a
190 longer arm (i.e., lower reaching velocity) [14]. Additionally, manipulating cues (e.g., pitch, loudness) of sounds related to
191 the level of applied strength when tapping a surface can result in changes in perceived tapping strength, own ability to
192 tap and emotional state; it was found that participants felt more able to tap, more pleasant and were less physiologically
193 aroused as shown by their galvanic skin response when the sound indicated high vs low levels of strength applied
194 [87, 89]. Critically, evidence shows that feelings of agency and spatio-temporal congruency between action and auditory
195 manipulation are essential for these effects to emerge [63]. There is also related work, from the field of soma design, on
196 targeting sensory misalignment for explicitly disrupting sensory perception to evoke estrangement or for disrupting the
197 habitual as a path to design [101]). Apart from these altered natural sounds, artificial sounds played in synchrony with a
198 bodily action, but which do not provide explicit feedback on the performed action, have been shown to induce changes
199 in body-perception. For example, accompanying body movements with the sound of a "creaky" door can make people
200 feel stiffer [86], while accompanying joint movements with pre-recorded sounds and vibrations produced by a robotic
201 arm can make people feel "robotised" [52]. Another related work describes a wearable, *Squeaky/Pain*, that employed
202
203
204
205
206
207
208

209 sounds of squeaky wood accompanying bodily movement to create disturbing experiences that augment the wearer's
210 somaesthetic awareness of their body as well as who was in control of it [23]. Such literature has led researchers to
211 explore the opportunities that the sonification of a movement offers in terms of addressing psychological barriers to
212 physical activity, such as perceived body weight, sized and physical capabilities while engaged in physical activity. Our
213 work aims to contribute to this body of work by addressing two specific gaps highlighted in the next two subsections.
214
215

216 **2.2 Changing Body-perception Through Sound to Facilitate Physical Activity**

217 Existing technologies aim to facilitate and support physical activity through encouraging self-tracking and goal-setting
218 behaviour, providing quantitative feedback on physical activity (e.g., amount of activity, goals achieved) [16, 50].
219 However, only providing feedback on physical activity performance (e.g., Fitbit app) is often insufficient to ensure
220 adherence and facilitate physical activity, especially for those who struggle to engage [108]. An alternative approach is
221 to tackle the underlying psychological barriers or needs that prevent people from engaging in physical activity (e.g.,
222 low self-esteem and motivation, negative body feelings, low self-efficacy, and related affective states and moods due to
223 such feelings) [75]. Instead of just monitoring the amount of activity, a new line of research has been rethinking the
224 design of physical activity technologies by embedding these psychological factors into the design process [57, 68, 83].
225

226 Extensive research has focused on the use of music to promote physical activity adherence, increase exercise
227 participation, leading to behavioural changes [42], due to its ability to induce positive emotional states [46, 102]. More
228 generally, positive influence of music on physical activity has been largely reported. Different mechanisms have been
229 pointed out, such as the role of rhythmic entrainment [44]. For example, the influence of tempo has been studied on
230 rowing performance [74] and on treadmill exercise [25]. Furthermore, rhythm and musicality have been investigated
231 for their potential in helping to enhance physical fitness, including cardiorespiratory endurance and muscular fitness,
232 albeit with conflicting findings (for a review see [36]). Music has also been shown to influence perceived exertion
233 [73]. In particular, the possibility to control sound (called musical agency) has been demonstrated to play a key role in
234 reducing perceived exertion during strenuous physical performance [31] or beneficial for motivation, learning and
235 performance in running [109].
236

237 Beyond addressing emotional states through music, several studies have explored the previously identified potential
238 of auditory feedback to change mental body representations in the context of facilitating physical activity in physically
239 demanding and undemanding exercises for active and inactive adults. Some earlier research has shown that altering the
240 body-produced auditory feedback can be an effective way of changing body-perception, and in turn related affective
241 state (feeling good about oneself and one's capability), and actual movement. Some of our previous work [91, 95]
242 shows that listening to one's own footstep sounds, which were modified in real-time in terms of their frequency
243 spectrum, may change how people perceive their body size and weight, which in turn affects the way they walk and
244 their emotional state in terms of valence and arousal. For instance, listening to high-frequency footsteps sounds while
245 walking has been shown to make people feel lighter and quicker; happier and aroused; and adapt their behaviour so
246 that it is consistent with having a thinner body (i.e., a more dynamic swing and a shorter heel strike), as compared to
247 the feelings and behaviors elicited by low-frequency footsteps (i.e., feeling heavier and slower) [91]. These positive
248 effects of the high-frequency footstep have also been identified in more physically demanding exercises (i.e., gym-step,
249 stairs-climbing), showing the potential of this approach to motivate and facilitate physical activity [15]. A similar set-up
250 has been tested and shown promising for physical rehabilitation of people with chronic pain [92] and stroke [34], and
251 for studying anomalous body experiences in people with symptomatology of eating disorders [90]. However, rather
252 than sonification of a movement, the approach used in these studies was to alter the characteristics of a natural action
253
254
255
256
257
258
259
260

261 sound (the footstep sound) to look like the one of a heavy or light person. No artificial sonification of movement was
262 explored.

263 In addition to altering the body-produced sounds, metaphorical movement sonification has potential to enhance
264 body-perception and facilitate physical activity. Artificial movement sonification, where body movement is tracked and
265 mapped into real-time auditory feedback, has often been used in the context of sports and physical rehabilitation to
266 provide information on movement (e.g., on hand-water interaction while swimming [15]) and help movement execution
267 and control (for recent reviews see [3, 79]), and movement awareness in clinical condition (e.g., physical activity for
268 people with chronic pain [83] to overcome anxiety). Such studies however have not investigated effects on body size and
269 physical capabilities perception. Subsequently, both quantitative [55] and qualitative studies [56] showed that movement
270 sonification with natural metaphors (e.g., wind, water) enhances various aspects of body-perception, emotional state
271 and movement in a variety of exercises, specially for physically inactive individuals. Recently, a quantitative study
272 investigated the effects of ascending sounds when accompanying a simple arm raise movement [55]: the ascending
273 sound eased the movement and enhanced several body feelings (i.e., lightness, speed, (less) tiredness, capability and
274 motivation to perform the movement). This was a first attempt to investigate the effect of pitch sounds on proprioceptive
275 awareness and bodily movement, which only explored the effect of dynamic pitch in a basic upward movement with
276 relatively little bodily displacement.

277 However, most of these studies have focused on light exercises (e.g., arm raise) and only two studies have explored
278 strength exercises. The quantitative study reported in [69] showed that movement sonification using a series of musical
279 chords (rather than a continuous sound changing in pitch, as the one used in this study) can motivate physically
280 inactive people during a downward squat exercise being seen as rewarding the completed movement [69]. The focus of
281 the study was on understanding the effect of expectation-related musical structures (e.g., stable vs unstable cadence)
282 embedded at the end of a movement sonification on the depth of a squat and on the repetition (time to return) in a
283 sequence of squats. Effects on perception of one's body size and capability were not investigated. More recently, we
284 used a qualitative-only approach in [57] where we provide evidence of positive effects of ascending pitch sounds on
285 inactive participants performing strength exercises (squats and steps-up). However the study included only 7 inactive
286 people and 7 very highly active people and used only qualitative methods. No quantitative measures of the effects on
287 behaviour were gathered. While this small qualitative study provides some initial understanding of how sonification
288 may impact body-perception in strength exercises, an in-depth quantitative analysis of this effect is needed to inform
289 the development of a sonification framework. In addition, rather than only looking at people at the two extreme levels
290 of fitness (very inactive vs highly active), it is important to also consider low-but-active people as they represent a
291 critical and large part of the population that need to be supported. In this study, we aim to address these gaps in strength
292 exercises through a quantitative method and across inactive and low-active people.

301 **2.3 Interaction between Movement Sonification and Sound Directions**

302 Sound changing pitch leads to the perception that the sound is moving in a certain direction. Recent studies on body-
303 perception outside the context of exercise have looked at the effect of sounds changing in pitch on body-perception.
304 Drawing on the proposed metaphorical cross-modal correspondence between sound pitch and vertical movement (i.e.,
305 ascending pitch and upward movement, descending pitch and downward movement) [27], previous investigations focus
306 on the effect of dynamic pitch on the mental representation of one's finger length when paired with a finger pulling
307 action [97]. In a controlled experiment, adult participants were asked to press and pull their finger up or down while
308 presented with brief pure-tone sounds of rising, falling or constant pitches. The study found that the pairing of the
309
310
311
312

313 finger pulling action with an ascending pitch sonification results in people perceiving their finger as significantly longer
314 than with a descending or constant pitch regardless of the vertical pulling direction (i.e., pulling up or pulling down).
315 This suggests that pitch direction rather than the cross-modal correspondence between pitch direction and vertical
316 movement trajectory alters the perceived finger length. [67] investigated the same effect of ascending or descending
317 sound while having their finger pressed or pulled but this time along the horizontal axis (i.e., pointing left/right), and
318 found no effects; indeed, the cross-modal correspondence between dynamic pitch and horizontal movement has been
319 shown to be less of an automatic mapping [65, 77]. Together, these findings suggest that the spatial metaphor of dynamic
320 pitch is sufficient to alter mental body representations, yet only when paired with vertical movement.
321
322

323 Despite these findings, no study has addressed the interaction between sound direction and movement direction in
324 the context of physical activity. Two differences exist with the finger pulling situation. In the finger pulling, the same
325 physical force is in place, the other hand pulling the finger away from the attached hand. In the context of physical
326 exercise instead, the force exerted by the body in the two vertical opposite directions requires very different muscle and
327 movement activity that may interact differently with the direction of the sound. Hence it remains to be investigated
328 whether the positive effect of ascending pitch on body-perception holds across both upward and downward movement
329 directions, when the extent of bodily displacement is increased (e.g., movement of the entire body as in squats vs.
330 part of the body as in finger pulling or arm raises), and for a more demanding strength exercise. Our current study
331 will precisely investigate this: in two experiments, we employ similar sounds, ascending and descending in pitch, to
332 investigate their effects on body-perception and movement behavior when accompanying body movement during a
333 physically demanding strength exercise composed of two directional phases, upward and downward, which are both
334 effortful (i.e., squats).
335
336
337
338

339 3 EXPERIMENT 1: METHODS

340 Experiment 1 aimed to understand how the direction of the dynamic pitch sonification (i.e., ascending or descending
341 pitch) with respect to the direction of the body movement (upward or downward) interact with the effects on body
342 feelings, experience quality, and actual movement [55, 97] in the context of a strength exercise. The experiment was
343 conducted remotely (i.e., in participants' homes) due to the COVID-19 restrictions at the time.
344
345

346 Experiment 1 was a mixed methods experiment, which was approved by the UCL Research Ethics Committee
347 (reference number 5095/001).
348

349 3.1 Participants

350 Participants were recruited through the University subject pool and social media. Experiment 1 was conducted entirely
351 remotely. Inclusion criteria: 18 years or older; no known chronic, mobility or hearing conditions; able to perform at
352 least 5 consecutive unweighted squats; not pregnant. In Experiment 1, additional requirements were an Android phone
353 (OS 6 or above) and ear/headphones for using the app. The study was remote via MSTeams, so participants needed a
354 computer and webcam. 22 adults participated (Age: Mean=25.05 years, SD=3.08, Range=22-34; 12 men, 10 women).
355
356

357 3.2 Exercise Selection

358 The squats exercise was chosen because it involves full-body displacement and both downward and upward movement,
359 hence enabling the experimental manipulation of movement direction. It is one of the most effective and frequently used
360 exercises to build muscle strength, enhance athletic performance and minimize injury potential [28, 80]. It is linked to
361 many everyday tasks (e.g., lifting objects) and is commonly used in rehabilitation after joint- or knee-related injury. The
362
363
364

365 unweighted variation (i.e., body weight squat) was chosen to ensure participants' safety regardless of physical activity
366 level or access to equipment. While the focus was only on one exercise across the two studies, squats is interesting
367 because of the strength challenges it poses in both vertical movement directions. It also complements previous work
368 focused on arm movements. In addition, squats involve bending of body segments (legs in this case) rather than just a
369 vertical displacement of a rigid arm bringing complexity of the secondary horizontal displacements of individual body
370 parts beyond the main vertical one. It also involves the use of a variety of muscles across the middle and lower body
371 (lower back, glutes, various upper and lower leg muscles). As such, the learning may provide initial insights on the
372 effect that sonification may have on a variety of exercises that present one or both directional demands in addition
373 to the involvement of a variety of body parts that may be engaged in different secondary minor displacement (e.g.,
374 jump-squat, cube step-up, planks, pull-up bar exercises, arm raise with weights), involve upper or lower body parts as
375 well as bending of limbs. We call main displacement the largest one and the one perceived as characterizing the main
376 direction of movement.
377
378
379

380 3.3 Experiment Design

381 The experimental design was a 2x2 within-subject remote experiment, with two independent variables and two
382 levels each: the first independent variable was movement direction with levels upwards and downwards. The second
383 independent variable was pitch direction of a simple musical sound with ascending and descending levels. We focused
384 on the changes effected by the sound in terms of direction of movement, not on correct movement performance. The
385 dependent variables included behavioural measures, and quantitative and qualitative self-report data and were selected
386 in accordance with previous studies in this area [55, 57].
387
388
389

390 **Body feelings:** Self-reported changes in body feelings were quantified using the body feelings questionnaires used
391 by related studies (e.g., [55, 56, 91, 95]). Our version was comprised of 12 items (7-point Likert-type response) about body
392 perception (*Strength, Tiredness, Comfort, Capability*), movement perception (*Difficulty, Speed, Control and Coordination*),
393 feelings of oneself being producing the sounds heard (*Agency*), and about motivation to do the exercise. Finally, an
394 open-ended question to describe the perceived changes. The selected body perception dimensions represent critical
395 perceived barriers to engagement with exercises, including strength exercises such as squats. The movement perception
396 dimension relates to important factors in exercise executions. Agency (feeling that one is driving the sound) is critical
397 for sonification to have an effect [63] on body perception alteration.
398
399

400 **Affective experience:** The valence/pleasure and arousal subscales (9-point Likert-type response items) of the
401 self-assessment manikin (SAM) [6] were used to assess emotional or affective responses, as measured in related studies
402 [55, 97]. Emotional responses here refer to a short-time process in response to an eliciting event, in this case the
403 experimental condition, and which can be measured by looking at affective reports, physiological reactivity and overt
404 behavioral acts [6]. Here we measure only one of the systems as we focus on affective reports. We note that changes in
405 emotional or affective experience contribute to participants' overall experience quality. Such changes may be due to
406 changes in perception of oneself or in the overall exercise experience. Such distinctions, and other aspects contributing
407 to the experience quality, are explored through the follow-up interviews.
408
409

410 **Movement behaviour:** This was measured using phone sensors (*accelerometer, gyroscope*). The data captured by the
411 rotation vector (Y-axis) was normalized, visualized and cleaned. Next, 8 movement variables were extracted for each
412 squat repetition using MATLAB [55]. These were the peak and mean movement angle between start and end position;
413 and time, velocity and acceleration from minimum to end position (i.e., for the upwards movement) and from end to
414 start position (i.e., for the downwards movement).

3.4 Materials

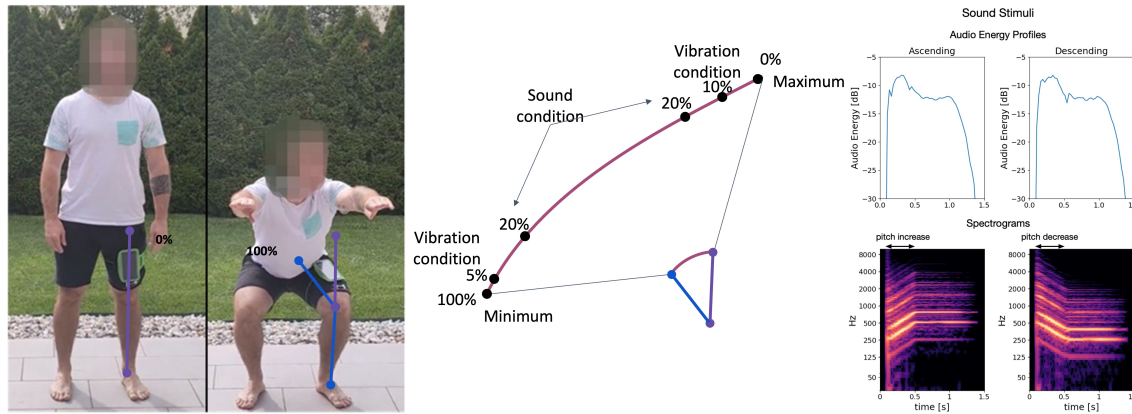

Fig. 2. Smartphone on thigh, calibrated between maximum standing and minimum comfortable squatting position; they correspond respectively to 0% and 100% of the total movement range (left). Movement angle thresholds to trigger the sound for upward and downward squats and for vibrotactile and sound conditions (middle). Audio energy profiles and spectrograms of the sound stimuli: Ascending and Descending sounds (right). Note that the mapping between percentage of movement and movement degrees varied for each participant since the range of movement varied for each participant and was determined during the calibration. For a participant able to squat 100 degrees, the correspondence between percentage of movement and degrees was one-to-one.

3.4.1 Experimental Application. A smartphone application was developed for the study, based on [83]. The application used built-in phone movement sensors to track, measure and sonify participants' movements. Participants' phone was attached to their thigh with an armband and a strap (Figure 2). The app was calibrated to each participant's maximum (i.e., standing) and their lowest comfortable squatting position (Figure 2-left and middle) using the device's sensors. The maximum and minimum calibration points were considered respectively as 0% and 100% of the total movement range. A change in movement angle triggered a continuous synchronous sound. Connected headphones were used to ensure a good sound quality. We chose a sound stimuli that was already used in a previous study [55] on lift arm exercises. The sound appears as two percussive notes (forming a fifth interval such as C-G, considered as consonant and stable in musical theory, and being predominant harmonics of a musical sound), with a short attack (peak at 0.2 s), decay (0.3 s) and sustained part of 0.5 s, and a release (intensity diminishing sharply during 0.3s) with a reverberation effect. This sound envelope is shown in Figure 2 (right) where the audio energy is reported. The total sound duration was fixed to 1.3 s. As shown in Figure 2 (right-bottom) where the audio spectra are displayed, the sound had a rich spectral content as they were initially created using marimba sampled (which give the percussive attack) and modified to ensure a longer sustain. For the experiment, the pitch direction of the musical sound was manipulated (using a phase vocoder), during the first 0.5 s for the sound, to create a continuous ascending pitch change of one octave (frequencies being multiplied by two) or a continuous descending pitch change of one octave (frequencies being divided by two) or a continuous descending pitch change of one octave (frequencies being divided by two), based on [55] (Figure 2). The pitch variation is clearly visible in Figure 2 (right, bottom). Loudness was normalized across both sounds. To account for the difference in the recommended movement time between the squat ascent and descent [66], when squatting upward the sound was triggered as participants reached 10% of the movement angle and 20% when going down. The raw sensor values were stored on participants' smartphones and later shared with researchers.

3.5 Experiment Procedure

Before the experiment, participants completed a pre-screening survey to check eligibility and installed the app. They gave informed consent for the study. A smartphone armband and strap were sent by post. At the start of the study, participants were explained the experimental procedure by a researcher on MSTeams and prepared the materials (i.e., app, headphones/earphones, smartphone band). Next, they filled out the demographics questionnaire and watched instructional videos for attaching their phone to their thigh and performing the exercise. Each session was video recorded with consent. First, was the **practice phase**, where the participants strapped their phone onto their thigh, and calibrated the device where they set the maximum (i.e., starting) and minimum squatting position. They performed 3 squats to check if the application worked correctly. Second, during the **experimental phase**, participants performed 4 sets of 5 squats with a short break (1-2 min) between each set. This phase had **full-squat sonification** where both downward and upward squat movement directions were accompanied by sound. Each set of squats consisted of either congruent movement-sound pairing (i.e., downward movement with descending pitch, upward movement with ascending pitch) or incongruent pairing (i.e., downward movement with ascending pitch, upward movement with descending pitch). Each participant performed four sets of squats, one for each possible pairing. To control for potential order effects, the order was fully randomized. The participants took a break after each set (reminded by the app by voice message). Movement data was collected throughout this phase. Next, participants performed 4 squats in the **self-report phase**, stopping after each squat to fill out the body feelings and SAM questionnaires. This phase had **half-squat sonification** where only one direction of the squatting movement (either up or down) was sonified, to assess the effect of each pitch direction on each movement direction. There were 4, fully randomised conditions (ascending sound-up movement, ascending sound-down movement, descending sound-up movement, descending sound-down movement). Movement data was not collected in this phase. This was because we had already collected the movement data in the previous phase and the focus in this phase was not on the movement but on how participants perceived the sound and its effect on their movement - thus the focus was removed from the movement itself. Finally, at the end of the experiment, qualitative changes in bodily feelings and emotional state were assessed using a short semi-structured interview (around 10 minutes). In the interviews, participants were asked to elaborate upon their experiences during the entire experiment related to their body feelings, movement perceptions and experience qualities, as well as the reasons behind these experiences. During the interview, participants were asked to think about all the four conditions they experienced during the self-report phase. They were then asked to describe their experiences during the four different conditions. We asked them if their experiences differed between conditions and in what way? We also asked participants about how they would compare the experience of going up with the ascending pitch vs going up with descending pitch? We also asked them about the converse: i.e. how they would compare the experience of going down with the ascending pitch vs going down with the descending pitch. We then queried which sound (regardless of movement direction) they preferred the most and why. We further probed how the sound made them feel. Next, we asked how they felt about the movement of squatting down vs standing up from the squat and why they felt that way. We then asked participants about which sound-movement combination they preferred the most and why and how it made them feel (light, heavy, fast, slow, strong, tired, etc.). We finally asked participants if any of the sounds or specific sound-movement combinations helped with their movement and in what way. Before we ended the interview, participants had the chance to add anything we may have missed. The interview was audio-recorded. Participants finally emailed the movement files to the researchers.

3.6 Data Analysis

We collected both quantitative data, including self-report and movement sensor data, as well as qualitative interview data. In this section, we describe the analysis approach for both.

Quantitative data analysis was done using the “ARTool” package in R [108] using 2x2 repeated measures ANOVAs on aligned rank transformed (ART) data with ‘*movement direction*’ and ‘*pitch direction*’ as within-subject factors. Separate aligned rank transformed ANOVAs were conducted for all self-report items. Movement data was obtained from sensors automatically and checked for outliers. Normality of model residuals was tested using the Shapiro-Wilk test. No outliers were detected but the model residuals for all dependent variables showed large normality violations. After testing various transformations unsuccessfully, we carried out non-parametric analysis for all movement variables: velocity, acceleration and time measurements were submitted to separate 2x2 repeated measures aligned rank transformed ANOVAs with ‘*movement direction*’ and ‘*pitch direction*’ as within-subject factors. Since angle data (i.e., peak and mean movement angle) was measured for each squat rather than each movement direction; it was analysed using separate one-way repeated measures aligned rank transformed ANOVAs with ‘*condition*’ (congruent or incongruent) as the only within-subject factor. The significance level for all statistical tests was fixed at an alpha level of 0.05 and effect sizes $\eta p2$ were calculated [18].

Qualitative data analysis of each participant interview was done using thematic analysis [7] as follows. We transcribed interviews verbatim. Participants’ responses to open-ended questions from the self-report questionnaires were combined with their associated interview transcripts for analysis. Each transcript was then analysed following the Braun and Clarke approach to top-down thematic analysis [7]. The aim of the follow-up interview was to better understand participants’ experiences related to each of the sounds and sound-movement pairings throughout the experiment. Hence, the transcripts were analysed deductively, with codes based on the body feelings, movement perceptions, and experience qualities perceived during the different experimental and self-report conditions. Subsequently, the codes were grouped into larger themes and subthemes in relation to the research question.

4 EXPERIMENT 1: RESULTS

Three main themes emerged from the quantitative and qualitative data on the effects of movement sonification on (i) body feelings, (ii) movement behavior, and (iii) experience qualities. Quantitative and qualitative results are reported together for completeness.

4.1 Effects of Movement Sonification on Body Feelings

Analysis of self-reported data shows a significant effect of movement direction on perceived movement ease. The effect of pitch direction on various body feelings was significant: when movement was accompanied by ascending sound, participants felt significantly lighter ($F(1, 21) = 13.21, p = 0.002, \eta p2 = 0.39$), less tired ($F(1, 21) = 7.64, p = 0.012, \eta p2 = 0.27$), more capable ($F(1, 21) = 6.30, p = 0.02, \eta p2 = 0.23$), more motivated ($F(1, 21) = 13.63, p = 0.001, \eta p2 = 0.39$), and perceived the movement to be easier ($F(1, 21) = 10.15, p = 0.004, \eta p2 = 0.33$) (Figure 3). They also perceived the downward squat to be more difficult than upward ($F(1, 21) = 4.62, p = 0.043, \eta p2 = 0.18$). There were no other significant effects or interactions.

Follow up interviews showed that most participants discriminated between ascending/descending sounds, associating ascending pitch as positive and descending as negative regardless of the movement direction it sonified, based on their previous experiences of similar sounds. P3 said, “[...] in a video game a low-pitched sound is like you lost the game.

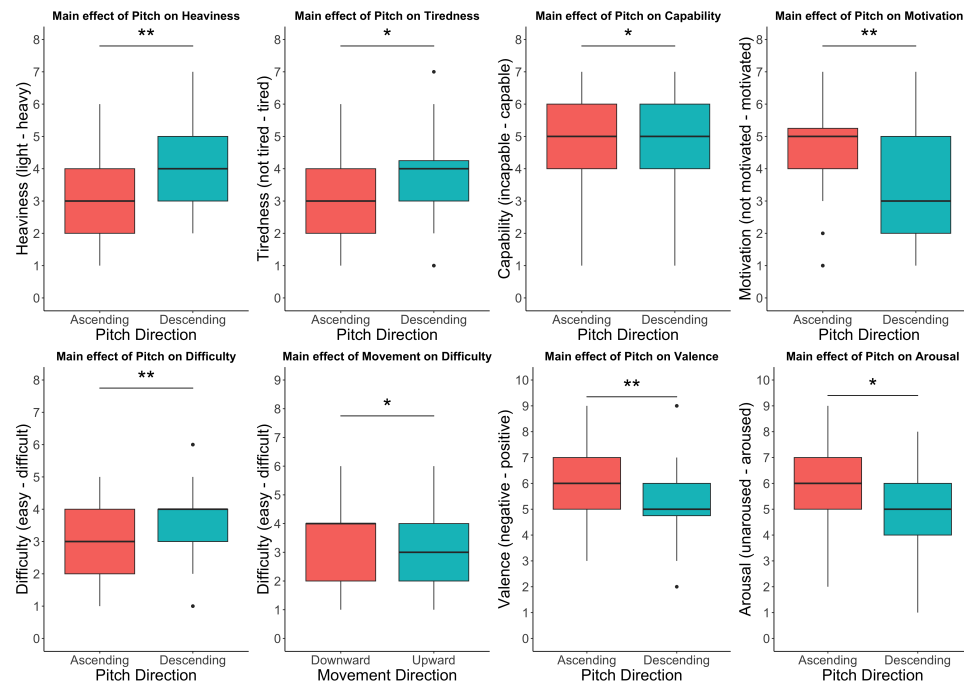

Fig. 3. Boxplots for body feelings and experience qualities significantly influenced by pitch direction or movement direction (* indicates $p < .05$, ** indicates $p < .01$).

That is what it sounded like when I heard the descending sound. A high-pitched sound means I successfully passed the level.” Qualitative results for ascending pitch were in-line with the quantitative self-report results mentioned above. Descending pitch made participants commonly feel heavier and less capable regardless of movement direction: P22 said, “descending sound was diffusing ... it would help me sleep rather than exercise.” Ascending sounds were commonly associated with correct movement and descending sound with incorrect movement; the validation provided by the ascending sound acted as a motivation to continue the exercise. P2 explained, “Getting positive reinforcement makes you feel good. So you get that approval from a noise saying you did the movement correctly. This empowers you to do more”. Descending pitch had the opposite effect; its association with failure made participants reject the sound, like P20: “As the pitch was decreasing, it felt like I failed or did something wrong in the squat and I felt unmotivated to continue [...] that sound did not feel like it came from me, I mean no one wants to fail, right?” Ascending pitch with ascending movement (congruent sound-movement pairing), facilitated movement and amplified feelings of lightness associated with the sound. The ascending sonification reduced perceived difficulty of the upward movement and the ascending-up sound-movement combination enhanced capability, increased perceived speed, and perceived quality of movement; P19 said, “With the ascending sound, it felt like I went up really fast and that speed just carried me. It felt like I went up more than during other squats. Moreover, the ascending-up pairing was perceived as the most synergetic and in-sync with one’s movement, resulting in a higher perceived sense of agency over the sound. With this pairing, participants described feeling like a decompressing spring as they squatted up; this feeling intensified through the ascent and was the most salient at the top of the squat, facilitating not just the ascent but movement completion and progression onto

625 the next squat: P20 said, *“The rise in pitch made me feel like my ascent was much faster and springier. It made me feel like I*
626 *could go for another round just to feel that springiness again.”* About a quarter of the participants enjoyed the descending
627 sound on the descent, perceiving their movement as controlled and less demanding. Feelings of heaviness associated
628 with the descending sound enhanced the perceived speed, quality, and amount of the downward movement, as P7
629 said: *“When the descending sound came as I was squatting down, it felt like I was pulled down by the sound and a bit*
630 *heavier, faster and stronger, sinking deeper into the squat.”* However, some other participants perceived the descending
631 sound as negative and demotivating even on descent; one described it as a *“battery losing its power”* (p1). Moreover, the
632 lack of upward sonification following the descending-down pairing in the self-report phase (only half of the squatting
633 movement was sonified) impeded the subsequent upward movement, increasing the difficulty of the squat and reduced
634 motivation to continue with the exercise. However, sonifying both squat directions increased the sense of agency and
635 connection between the sounds and one’s movement. P11 said, *“The descending sound when I am going down makes*
636 *me feel like I am going to get stuck because I have no energy to go back up. But when followed by an ascending sound it*
637 *worked because it balanced itself out. So, I am being pulled down and then pushed up.”* (p11) Others felt accompanied by
638 full-movement sonification: P11 felt that *“When the sound went along with the movement, it felt like I was being pulled*
639 *down and pulled up. So, it felt like I was not doing the exercise on my own.”* We note here that some participants used the
640 terminology of being pulled but this was not primed by the researchers.
641
642
643
644

645 4.2 Effects of Movement Sonification on Movement Behavior

647 Results show a significant effect of movement direction: participants took significantly less time to complete the
648 downward movement compared to the upward one regardless of pitch direction ($F(1, 21) = 8.41, p = 0.009, \eta p2 = 0.29$),
649 as expected (Figure 4). Movement velocity ($F(1, 21) = 7.62, p = 0.012, \eta p2 = 0.27$) and maximum acceleration
650 ($F(1, 21) = 24.41, p < 0.001, \eta p2 = 0.54$) were significantly greater when squatting down compared to going up
651 regardless of pitch direction. Pitch direction of the sound affected movement acceleration as participants had greater
652 maximum acceleration with the descending compared to ascending pitch regardless of movement direction ($F(1, 21) =$
653 $6.20, p = 0.021, \eta p2 = 0.23$) (Figure 4). There were no other significant effects. Behavioral measurements highlighted
654 only acceleration effects of descending sound, but qualitative results were nuanced. Participants perceived ascending
655 pitch as facilitating the squat, reducing perceived difficulty, and enhancing perceived speed and quality of movement. In
656 contrast, most did not enjoy the descending pitch, as they felt it impeded the movement and reduced its quality. Further,
657 pairing the *“positive”* ascending sound with upward movement of the squat seemed to enhance movement performance.
658 P2 said: *“The hardest part of a squat is coming up so having the positive [ascending] sound on the way up made me feel*
659 *better than when I went down with that sound.”* Thus, P2 did not find pairing ascending sound with the down movement
660 (incongruent) as beneficial. Most participants found incongruent full-squat sonifications (pitch direction different from
661 movement direction, e.g., ascending-down) unexpected and weird. For example, some participants described the sound
662 as *“lacklustre and redundant”* (p15). Moreover, the misalignment between the sound and movement, reduced the sense
663 of agency for some. P13 said: *“It was a motivating sound, but did not fit the downward movement; I felt less connected*
664 *to it. It was nicer than no sound but more neutral and awkward.”* Despite this, most participants reported little or no
665 effect of congruency between sound and movement on actual or perceived body movement. Overwhelmingly, full-squat
666 sonification was perceived as more beneficial to facilitating physical activity compared to half-squat sonification and
667 people reported *“missing the full sonification”* (p9).
668
669
670
671
672
673

674 About a fifth of the participants reported a slight or even a complete lack of effect of the full-squat sonification
675 on their movement perception, body feelings and experience quality. This seemed common with participants who
676

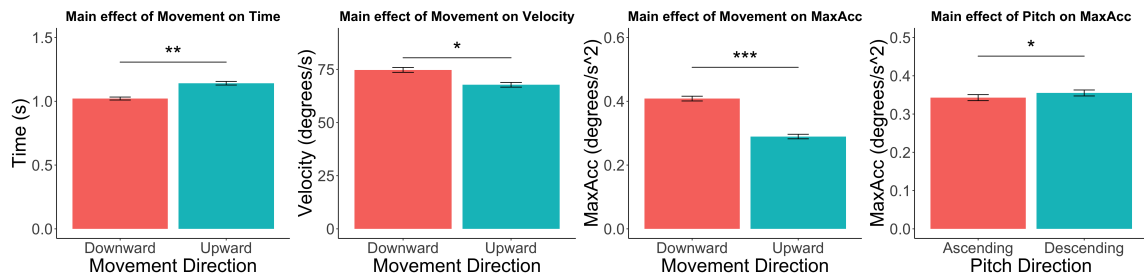

Fig. 4. Means and standard errors for movement time, velocity and maximum acceleration indicating several significant main effects of movement direction and a significant main effect of pitch direction on maximum acceleration (* indicates $p < .05$, ** indicates $p < .01$, *** indicates $p < .001$).

were less used to squats and hence potentially too focused on their movements and the squat count, thus ignoring the sonification altogether. Some participants completed the sets of 5 squats too quickly, resulting in sensory overload and lowering their ability to distinguish between different sounds and pairings. P16 reported, “Because I was doing the squats so quickly, the two sounds blurred into one. There were a lot of sounds and squats at the same time. [...] If I slowed down, maybe it would have had a different effect.” (p16) Some participants suggested that the number of repetitions was too small for the movement sonification to elicit any salient effects. A few found it too easy. A low sense of agency over sound, also often accompanied a complete lack of elicitation of effects on movement perception. A quarter of the participants had a hard time connecting the simple musical sound to their squatting movement. They argued the sounds were unfamiliar to how their body sounds, hence distancing themselves from the sonification. P14 said: “[...] I strongly disagree with those questions about agency. I’ve had my body for a long time, and I’ve never heard it do anything of that kind.”

4.3 Effects of Movement Sonification on Experience Quality

Emotional responses to the stimuli were measured to assess changes in the affective experience of participants, which contribute to the overall experience quality. Results showed a significant effect of pitch direction both on self-reported valence and arousal: Participants felt more positive ($F(1, 21) = 8.56, p = 0.008, \eta p^2 = 0.29$) and more excited or aroused ($F(1, 21) = 4.69, p = 0.042, \eta p^2 = 0.18$) with the ascending compared to the descending pitch regardless of movement direction (Figure 3). There were no other significant effects of movement direction or any other interaction effects. Results were supported by interview findings. Participants preferred the ascending pitch as it was perceived as more energetic, stimulating and motivating, regardless of movement direction. Moreover, it was described as more awakening, energizing, evoking feelings of lightness, and useful when trying to be more “explosive” in performing the squat movement (i.e., high-intensity, short-duration movement), despite people showing stronger acceleration in the descending sound.

The descending sound with upward movement was the least preferred sound-movement pair due to perceived pitch and movement direction misalignment, making participants feel significantly heavier, demotivated, and less capable. The perceived ease of the ascent amplified the perceived incorrectness associated with descending sound regardless of movement direction. P8 said: “The upward squat with the descending sound was definitely harder, I felt more muscle tension and heavier.” The full-squat sonification (both up and down directions sonified) led to a feeling of bounciness or springiness, significantly increasing the perceived motivation, capability, and movement ease. Although this feeling

729 was evoked by just the ascending sound on the ascent, it was enhanced by continuous two-way sonification. The
730 full-squat sonification seemed to increase the perceived capability to complete the exercise. The evoked spring-like
731 experience helped to maintain squatting pace, facilitating more squats. P20 said, *“When both movements were sonified, it*
732 *enhanced the springy sensation and motivated me to do more reps. You saw I went down again for a few extra and that was*
733 *due to the sound; I let the sound guide me and felt like I could keep going.”* This spring-like experience was reportedly
734 enhanced when the pitch direction of the sonification matched movement direction (i.e., congruent sound-movement
735 pairing). In fact, almost all participants described the congruent pairing as more natural and logical, mostly based on
736 participants’ prior experiences of encountering such sound-movement pairings like P7, *“...we are used to these kinds of*
737 *sound effects in films and media, I associate a rising sound with something going up like your body moving up. ... this*
738 *association is intrinsic in our minds.”* However, about two-thirds of the participants argued that while congruency (the
739 alignment between pitch direction and movement direction) was logical, it was the contrast between the two sounds
740 that was beneficial to facilitating the movement. The majority of participants agreed the two movement directions of
741 the squat should be sonified by a different sound for maximum benefit: P6 explained, *“It was more important that the*
742 *two sounds are distinctive rather than which one is paired with which movement.”* P22 added, *“The two different sounds for*
743 *two movement directions are good as it keeps the exercise interesting, exciting. if I had the same sound for five reps, it would*
744 *be repetitive.”*

751 5 EXPERIMENT 2: METHODS

753 Results in Experiment 1 showed differences in effects for the ascending and descending sounds during squat exercises.
754 Participants overall felt more positive, lighter, less tired, more capable, and motivated, as well as perceived the movement
755 to be easier with the ascending compared to the descending pitch sonification. Moreover, greater maximum acceleration
756 was observed with the descending sound compared to the ascending sound regardless of movement direction. Further,
757 our results showed that the incongruency between movement and sound direction was disliked, and that the congruency
758 between movement and sound direction enhanced the sound induced body and emotional changes. The pairing of
759 upward movement and sound seems to enhance the positive sensations associated with the upward sound. On the
760 contrary, the pairing of the downward movement and sound enhanced the feeling of heaviness; for some participants
761 this was linked to feelings of “energy loss” but for other participants this feeling enhanced the perceived speed, quality
762 and amount of the strength downward movement.

765 Experiment 2 aimed to better understand the effects of the congruent full-squat sonification studied in Experiment 1
766 on body feelings, experience quality, and actual movement. Two control conditions were used to trigger comparative
767 reflection in participants: no sensory feedback and haptic feedback. In this experiment, we focused on inactive or
768 minimally active individuals (as defined in [37]) as previous works on movement sonification have shown that effects on
769 some aspects of body-perception, experience quality, and actual movement do not affect individuals with high physical
770 activity levels [56]. Also, some participants in Experiment 1 suggested the exercise was too easy for the sound to affect
771 the movement. As a secondary aim, we investigated the effects according to the individual’s actual physical activity
772 level, as the literature shows that some factors such as personal values may trigger different effects of the feedback [99].
773 The study was conducted in-person in a laboratory setting, which followed COVID-19 safety measures.

777 Experiment 2 was a mixed method study with squats exercises accompanied by movement sonification, also approved
778 by UCL Research Ethics Committee (reference number 5095/001).

5.1 Participants

Experiment 2 was conducted face-to-face in a laboratory setting. There was no overlap between participants from Experiment 1 and 2. Participants in Experiments 1 and 2 were a completely different set of people due to time gaps and experimental scenarios. In Experiment 2, additional criteria were no known skin issues (as they had to wear a device on the skin); self-identification as physically inactive. In addition, it was decided to recruit only women as participants. The reason was twofold: to maximise the power of our findings given the physiological differences (muscle physiology) between the genders and the number of participants we could recruit [2, 21, 39]; to ensure that the researcher collecting the data (a woman) and participants felt at ease during the placement of the electrodes on their upper body. Naturally, the findings from this second study cannot be generalized to a different gender as we will discuss in the limitations and future directions. Finally, to verify physical activity level, participants completed the International Physical Activity Questionnaire (IPAQ) [37] - half (N=10) the participants were physically inactive, while others (N=11) were minimally active. 21 adults (Age: Mean=24.24 years, SD=7.09, Range=20-41; all women) participated.

5.2 Exercise Selection

Same as in Experiment 1.

5.3 Experiment Design

There were two independent variables in the experimental design: a within-subject independent variable, sensory feedback, with three levels (sound only, vibrotactile only, and a no-feedback-control), and a between-subjects independent variable, participants' physical activity level, with two levels (inactive and minimally active). As in Experiment 1, the measured dependent variables included behavioral measures and quantitative and qualitative self-report data. Some changes in these measures were introduced for a better understanding of people's sensations across the body.

Body and movement feelings: Body and movement feelings were captured using a contextual Body Map using an iPad (Figure 5). A Body Map is a very visual qualitative design and research tool featuring "a pictorial outline of the participant's body." [17] While they are used in multiple disciplines (including Health, Sociology, Anthropology, and Design Research) [1, 17, 33] differently and with slightly different variations, in body-focused design research, Body Maps typically involve an outline of the participant's body onto which they draw their body experiences, including sensations and feelings (e.g. [1]). This allows participants to both reflect on, and document, their body sensations and feelings [1, 17, 33]. Like in other body-centered design research works (e.g. [57, 90]), we provided participants with "empty" outlines of bodies as templates to inscribe their sensations and feelings, which they did with color markers. Further, since Body Maps are visual representations of the participant's physical form [17] and we were targeting women participants, we chose body outlines with identifiable female traits (See Figure 5. Then, similarly to [57, 93], our Body Maps were contextual in the sense that they represented key moments in the activity, such as standing and squatting. Like in [57, 90] as well, keywords next to the Body Maps were included to help participants map and illustrate body feelings relevant to the exercise. Then like in [57], rather than to compare sensory modalities, we used Body Maps to support the participants' reflection on sensations on the body in general and the different body parts related to the sensory feedback; as well as on the impact of this feedback on their feelings about their body and movement. There was space to add notes for later discussion. Changes in movement feelings were quantified using 5-point Likert-type response items assessing participants' feelings of being in control of their movement, of movement guidance, and of goal motivation. These subscales were presented with the SAM questionnaire and with the same pictorial format [6].

Experience qualities: The valence/happiness, arousal/excitation and dominance subscales (5-point Likert-type response items) of the SAM questionnaire [6] were used to assess changes in feelings. Follow-up interview explored in more detail such feelings and their possible cause.

Movement behavior: This was measured using an Inertial Motion Unit (IMU) (see Materials 5.4) attached to the participant’s right thigh. Data treatment and extracted parameters were the same as in Experiment 1.

5.4 Materials

Fig. 5. (Left) A filled Contextual Body Map, showing effect on participant’s body and movement feelings during exercise. (Right) Waist belt with vibration module. 5 vibration motors were attached to the participant’s back.

5.4.1 Experiment Device and Feedback. A wearable device (Figure 1) was developed to deliver sound and vibrotactile feedback in response to participants’ movements, and to measure movement behavior. The device was based on [55, 56]. It integrated a wearable band with a wireless emitter (BITalino R-IoT embedding a 9-axis IMU digitized at 16 bits). The band wirelessly transmits movement data through WiFi using the OSC protocol to a laptop running Max/MSP (Cycling’74). The laptop stores raw movement data. A pair of wireless headphones (Sony WH-CH510) delivered sound feedback; a vibration module incorporated with the wearable device delivered vibrotactile feedback. The vibration module, based on [93, 98], consisted of five vibration motors (10 mm diameter) attached to the person’s back forming a vertical line along the spine (Figure 1); motors were connected to a microcontroller with an adjustable waist belt (Figure 5). The sensor was calibrated as in Experiment 1. Following this, the laptop detected and triggered sounds or vibrotactile feedback to accompany movement. To avoid extreme sensitivity, the threshold of movement angle to trigger the sound for both upward and downward squats was 20% in sound conditions but for the vibrotactile condition the threshold was 5% for upward squats and 10% for downward squats to counterbalance the existing delay of activating vibration. Feedback sounds were same as Experiment 1. We focused on full-squat sonifications with congruent movement-sound pairing (downward movement-descending pitch, upward movement-ascending pitch) for both sensory feedback conditions. For vibrotactile feedback, the 5 motors were activated in top-down or bottom-up sequences to generate motion [43] consistent with squat directions, based on [93]. Each vibrator was sequentially activated and vibrated for 434 ms, with 217 ms overlap between activations: the total duration of the vibrotactile sequence was 1.3 s, same as for the sound feedback. Vibration intensity for each motor in the sequence varied to emulate “bounciness” or “springiness” described for the sound feedback. The intensity was 135 for the first motor in the sequence, then 165 and

195 respectively for the second and third motors, and 255 for the last two motors (intensity values are related to the
vibration amplitude set in the microcontroller).

5.5 Experiment Procedure

The experiment was conducted in a lab. Participants gave informed consent and completed the IPAQ questionnaire. Once instructed on the experimental procedure, the vibration motors were attached to the participant's back along the spine by placing the first motor under the bone of the neck and the last motor at the horizontal line of the hip bone, ensuring all motors were equidistant. Next, the participants calibrated the device to set the maximum (i.e., starting) and minimum squatting positions, and practiced the exercise. Next, during the *experimental phase*, participants performed 3 sets of 5 squats. Movement data was continuously recorded during this phase, except during breaks between sets. Each set differed in sensory feedback received while performing the exercise (sound feedback, vibrotactile feedback, and no-feedback). The order of conditions was fully randomized. During the short break between each set, participants completed the body map and questionnaires assessing experience quality, and body and movement feelings. Finally, a short (10 minutes) follow-up semi-structured interview focused on participants' salient feelings about their body and movement behaviors and the comparison of body feelings across the three conditions, in a combination of their self-reported surveys. Here the body maps and the questionnaires filled by participants were used to ask questions and maintain a discussion with the participants about their experience on the exercise and the sensory feedback. The interview was audio recorded with consent. At the end, participants were debriefed with contact information in case of inquiry.

5.6 Data Analysis

Quantitative data analysis of questionnaire data was done, as in Experiment 1, using 3x2 repeated measures aligned rank transformed ANOVAs with feedback condition ('sound', 'vibration', 'no feedback') as within-subject factors and participants' PA-level ('inactive', 'minimally active') as between-subject factors. For significant interactions, separate aligned rank transformed ANOVAs were conducted for the two groups of participants. In case of significance, these were followed by paired t-tests corrected for multiple comparisons. While movement data was non-normal, deviations from normality were within an acceptable range as the data showed a linear pattern; therefore repeated measures ANOVAs were used to check interaction effects between feedback condition and PA-level. Wilcoxon tests followed significant effects.

Qualitative data analysis: Body maps were analyzed by linking the words reported by participants with the body parts they indicated by using colors (Figure 5). The analysis was done by providing an overview of differences in perceived body feelings with comparisons between the three sensory conditions with clustered bar charts. Findings were combined to better interpret the interview scripts. Interview audio recordings were transcribed verbatim. Transcripts were analysed using a combination of top-down and bottom-up thematic analyses [7]. Top-down codes used were changes in experience qualities, changes in perceived feelings, motivations, emotional states, perceived velocity, perceived movement behavior, guiding effect of sound, distracting effect and body control, These codes were mainly generated from the research goals on the difference between body perceptions and feelings, experience qualities, motivation, and physical activity behaviors during different feedback conditions. The analysis of experiment 2 was led by the second author who was present at the study and transcribed and analysed the data to identify themes. The resulting themes were discussed with the other authors, before finalising and writing up. Most participants (N=20) expressed preferences for squats with sound or vibration feedback so we focus on these conditions in various domains in results.

6 EXPERIMENT 2: RESULTS

6.1 Effects of Sensory Feedback on Body Feelings

Body maps yielded 163 records of body feelings for the three feedback conditions. Analysis suggests that sound is more capable of evoking body feelings during squats ($N_1=57$) and associated with a greater number of body parts ($N_2 = 10$) compared with the vibration condition ($N_1 = 55$ and $N_2 = 9$) and no-feedback condition ($N_1 = 54$, $N_2 = 8$). With vibration feedback, the most prominent feelings were of being flexible, fluid and fast, respectively linked with the back (flexible and fluid) and whole body (fast). A notable finding for sound feedback was a greater number of feelings targeted on the whole body were reported rather than single body parts; for instance, one-quarter of participants reported feeling flexibility and speed over the whole body. Thus, sound stimuli could lead to larger impacts on body sensation across the body, instead of body parts, around the signal inputs. In the no-feedback condition participants reported more negative body feelings (e.g., feeling heavy, not flexible or slow) than positive ones; more feelings associated with body parts from the middle body (e.g., upper thigh and hip), often associated with feeling heavy and strong.

Fig. 6. Boxplots for body feelings and experience qualities significantly influenced by the sensory feedback in Experiment 2 (* indicates $p < .05$, ** indicates $p < .01$, *** indicates $p < .001$).

The self-reported data shows a significant effect of the feedback condition on felt movement guidance ($F(2, 38) = 6.18$, $p = 0.004$, $\eta p^2 = 0.245$) and control over one's body ($F(2, 38) = 4.07$, $p = 0.025$, $\eta p^2 = 0.175$). Follow-up paired comparisons showed that participants felt less control over their body with vibration than with the no-feedback condition without sensory input ($F(60) = 2.53$, $p = 0.036$; see Figure 6). However, participants reported more movement guidance in the vibration compared with no-feedback condition ($F(60) = -2.42$, $p = 0.047$; see Figure 6). There were no significant differences between the sound and other two conditions. Further, there was a significant interaction effect between feedback condition and participant's PA-level in terms of reported movement guidance ($F(2, 38) = 4.54$, $p = 0.016$, $\eta p^2 = 0.193$). Separate aligned rank transformed ANOVAs were conducted for the two groups of participants, which showed a significant effect only for the "minimally active" participants ($F(2, 20) = 11.68$, $p < 0.001$, $\eta p^2 = 0.538$): for those participants, both the sound ($F(30) = -3.02$, $p = 0.013$) and the vibration feedback ($F(30) = -3.97$, $p = 0.001$) provided a larger sense of movement guidance than the no-feedback condition. There were no other significant effects.

Follow up interviews confirmed that both sound and vibration feedback affected participants' body feelings, but differently. Like in Experiment 1, participants related changes in sound pitch to dynamic objects such as pinball or spring, and synchronous generation along with squatting direction enhanced such experiences in flexibility. Half of the participants reported feelings of lightness and flexibility over the whole body: P01 reported, "I felt a kind of bounce feeling on my knee or probably over the body, because its sound effect is very like a spring, and it makes my body feel

989 *lighter anyway.*” Such feelings were most prominent at the beginning of the movement as many participants highlighted
 990 that the intensity of sound faded away at the end positions reducing the impact of the sound. P05 said, *“I noticed there’s*
 991 *a change in sound when I go up and down. [...] it’s very in sync with my squats, and has a fade away effect like strong at*
 992 *the beginning and weak at the end. . . . I think it’s a whole, but the strong intensity at the beginning might influence my*
 993 *body most.”* Two thirds of participants enjoyed the vibration feedback, as helpful, and eliciting feelings of flexibility and
 994 strength. P17 reported: *“The vibration was quite enjoyable. I have a bit of back pain and I felt that it went away with the*
 995 *vibration. So it made squats easier. When going up and down my back felt more flexible and stronger. It’s like adding fuel to*
 996 *my body. . . I felt stronger going up and down with my legs.”* For sound feedback, elicited body feelings depended on the
 997 interaction between pitch change (i.e. ascending and descending sound) and movement trajectory. Few participants
 999 reported that the sound effect in the downward vs. the upward part of the squats was stronger and they perceived it
 1000 as heaviness mainly on their upper thigh. The descending pitch generated a sensation of a dropping force when they
 1001 moved down. This resonates with findings of Experiment 1, in which participants reported feeling pulled down by the
 1002 sound. P15 reflected, *“... the sound when I move down, I feel a dropping force to sort of help my movement by following the*
 1003 *force created by sound when I went down.”* This sensation of a force being exerted by the sound feedback was regarded by
 1004 participants as an internalized force while the effect of vibration feedback was regarded as an externalized force, helping
 1005 them to perform squats. Participants linked sounds to dynamic daily objects, such as springs or pinballs, and perceived
 1006 themselves as those objects, with their properties. P19 said, *“The sound [...] made me feel like I was a spring. ... I imagine*
 1007 *a spring being very fluid, flexible. And because I had that image in my mind, I acted like the spring.”* Conversely, vibration
 1008 feedback was often described using metaphors such as an “add-on zip” or “hand rubbing” the back of participants and
 1009 associated with a helpful force exerted on their back P12 said, *“It felt like someone had put a zip on my back, but it*
 1010 *wasn’t uncomfortable, instead it was fun. I feel the vibrations quite smooth by going up and down, like someone is pushing*
 1011 *you up or pushing you down, so smooth.”* As with quantitative self-report results above, most participants described
 1012 the force being exerted by the sound and vibration feedback as beneficial in guiding squatting exercise. P08 said, *“For*
 1013 *the condition with no sound or vibration is like driving a boat on the sea, but for sound and vibration, it’s like you stop*
 1014 *on the river but you can float by the waves from the water, and it’s external driven force.”* Although their movement
 1015 angles triggered the feedback, most participants regarded the sound and vibration signals as reminders of when to
 1016 move upwards or downwards. P10 said, *“...it’s like a reminder, like setting an alarm clock at the time I need to go up and*
 1017 *down, so it pushes me to do the next movement.”* Both sound and vibration feedback were reported to make participants
 1018 focus attention on detecting changes in the feedback away from their working bodies. The same effect was differently
 1019 interpreted by different participants, leading to two perspectives: some participants regarded it as an interference to
 1020 fully perceive the sensations over the body, adversely affecting their correct position for performing squats, such as P19:
 1021 *“Vibration distracted me, so instead of keeping my back straight and squatting down backward, I thought I was squatting*
 1022 *forward.”* Others reported that this sensory distraction could provide a more relaxing experience, such as P13: *“With the*
 1023 *vibration, this time I focused all on my back instead of feeling my legs, so I felt much lighter on my legs and so relaxed so I*
 1024 *could easily do the 5 squats.”* P10 added, *“The sound can just distract attention - it takes focus away from the limbs and*
 1025 *thigh and tiredness is spread out.”*

1034 6.2 Effects of Sensory Feedback on Movement Behavior

1035 The feedback condition significantly affected peak angle ($F(2, 206) = 4.71, p = 0.010, \eta p^2 = 0.044$), mean angle
 1036 ($F(2, 208) = 5.27, p = 0.006, \eta p^2 = 0.048$), upward velocity ($F(2, 208) = 10.55, p < 0.001, \eta p^2 = 0.092$) and downward
 1037 velocity ($F(2, 208) = 7.35, p = 0.001, \eta p^2 = 0.066$). Participants squatted farther in the sound than vibration condition
 1038
 1039
 1040

($Z = -2.41, p = 0.016$). But, this comparison should be approached cautiously as the triggering angle differed between these conditions. Participants' movements were faster with no-feedback than with feedback, both for upwards (no-feedback vs. sound: $Z = -3.39, p = 0.001$; no-feedback vs. vibration: $Z = -3.83, p < 0.001$) and downwards (no-feedback vs. sound: $Z = -4.02, p < 0.001$; no-feedback vs. vibration: $Z = -3.10, p = 0.002$). When accounting for participants' PA-level, differences in squatting movement quality were more prominent for the inactive compared with the minimally active group. A significant interaction effect was found between feedback conditions and PA-level for 4 movement parameters: peak angle ($F(2, 206) = 8.96, p < 0.001, \eta p2 = 0.08$), mean angle ($F(2, 206) = 3.78, p = 0.024, \eta p2 = 0.035$), downward velocity ($F(2, 206) = 13.57, p < 0.001, \eta p2 = 0.116$) and downward time ($F(2, 206) = 6.27, p = 0.002, \eta p2 = 0.057$). Follow-up tests ran separately for inactive and minimally active groups, showed significant differences only for physically inactive participants, who displayed greater squatting peak angles ($F(2, 98) = 7.68, p = 0.001, \eta p2 = 0.14$) and mean angles ($F(2, 98) = 6.41, p = 0.002, \eta p2 = 0.116$) with sound than with vibration (Peak angle: $Z = -2.36, p = 0.018$; Mean angle: $Z = -2.54, p = 0.010$); slower downwards movement ($F(2, 138) = 13.92, p < 0.001, \eta p2 = 0.167$) with vibration than no-feedback ($Z = -4.88, p < 0.001$); and longer downwards time ($F(2, 98) = 4.58, p = 0.013, \eta p2 = 0.085$) with vibration ($Z = -4.56, p < 0.001$) and sound ($Z = -4.12, p < 0.001$) than with no-feedback.

Fig. 7. Means and standard errors for movement angle, velocity and time indicating significant main effect of sensory feedback and a significant interaction of sensory feedback with participant's PA-level on these movement parameters.

Qualitative results showed that while both sensory feedbacks affected participants' behavior in terms of guidance, the different nature of signals was associated with different aspects of guidance on squat behaviors. Some people perceived sound feedback as company that helped them combat the loneliness of self-exercise, similar to a voice chatbot. Indeed, sound feedback was often connected with the human voice, providing a feeling of being coached or accompanied, leading to a greater motivation to adapt behavior in terms of squat quality. P08 elaborated, "I feel like I'm being monitored [...]. So that pushed me to do squats in a more standard way. Probably because the sounds remind me of the process of a child's growth, we always listen to the guide from teachers or parents" Conversely, participants described vibration stimulation as intuitively guiding them. P10 explained, "I felt some strength at my back, and then the vibration gave me the feeling like a flow behind me, that helped me to straighten my back, or more accurately it reminds me to keep my back straighter." The vibration was mainly amplifying the sensations on the back and the vertical vibration trajectory

1093 provided directional guidance. Time delays adversely interrupted the effect from sensory feedback. Most participants
 1094 reported sound and vibration stimuli were slower than the time required to complete the squats, but chose to adapt
 1095 their behavior to follow the feedback after the first one or two squats. It affected the vibration condition more with
 1096 two reports of a severe time delay for vibration and consequently a low sense of agency. P09 said, *“when I did squats, I*
 1097 *realized that it didn’t come with me so I didn’t take the signal. My expectation was that I would squat and get up and down*
 1098 *and the vibe would immediately follow, but I realized that it didn’t so I discarded that signal.”*
 1099
 1100

1101 6.3 Effects of Sensory Feedback on Experience Quality

1102 Results showed a significant effect of feedback on self-reported arousal ($F(2, 38) = 9.612, p < 0.001, \eta p^2 = 0.335$; See
 1103 Figure 6 - right): Participants felt more excited or aroused with sound feedback compared to no-feedback ($F(60) =$
 1104 $-3.06, p = 0.009$) and also with vibration feedback compared to no-feedback ($F(60) = -3.198, p = 0.006$). There were
 1105 no significant differences between sound and vibration conditions, or effects on valence. In the interviews, participants
 1106 reported feelings of excitement associated with sound feedback. Over half enjoyed congruent sound pitch with squatting
 1107 movements, reporting elevated arousal and positive states, as in Experiment 1. P05 said, *“In the case of sound, I became*
 1108 *EXCITED, because I hear sounds that are like a pinball. It reminds me of how I used to play pinball with my sis and*
 1109 *it’s interesting, less boring, and mood goes up, I want to hear it again.”* Almost two thirds of the participants enjoyed
 1110 the vibration feedback and described it as “massage”, associated with relaxed feelings on the back or the whole body.
 1111 They reported more perceived strength over the body and becoming more athletic in ongoing squats. Participants
 1112 associated sensory feedback with rewards for movement. Almost all participants could identify the changes in sounds
 1113 with ascending and descending pitch that were congruent with movement direction and associated pitch changes
 1114 with dynamic objects with rewards. P12 said, *“... it was like game tones, it had that rewarding feeling that I crouched*
 1115 *down at the correct position and there’s a kind of ‘bingo’. ... like you got a gold coin for crouching down a bit.”* Two-fifths
 1116 of participants reported such incentive-based reward effects in the vibration condition. P08 explained, *“It’s like when you*
 1117 *play some drum games. ... how your bounces fit the vibration and I enjoy it, like a reward for completing a full squat.”*
 1118 The reward effect led to increased motivation in both sensory conditions in terms of quality and quantity. Nearly half
 1119 associated sound feedback with increased motivation in terms of velocity or number of squats, which contrasted with
 1120 behavioral results showing that the sensory feedback slowed down movements. Wanting more dynamic sounds for
 1121 positive experience resulted in higher motivation to perform more squats quicker. P10 said, *“...I know that two sound*
 1122 *tones were different because my movement changed, so I want to continue doing the movement to hear it. I love this sound.”*
 1123 Vibration being self-triggered by movement also increased the motivation to squat, but less than in sound conditions and
 1124 fully concentrated around the stimulated body part. Differently to sound, vibration feedback increased the motivation to
 1125 improve the quality, rather than the velocity or number, of squats. The pattern of vibration direction was perceived more
 1126 clearly compared to sound, and the congruency between vibration and squatting direction encouraged participants to
 1127 perform deeper to align with the vibration position. P13 said, *“It feels like a massage while moving, like playing a virtual*
 1128 *figure in a video game. ... the vibrations have a process from the bottom to the top and then top to the bottom, because I also*
 1129 *have such a process of movement. I try to follow the rhythms to reach the deep position when going down.”*

1139 7 DISCUSSION

1140 The first question that our study explored was whether vertical asymmetries in the effect of sonification, found in simple
 1141 exercises such as arm raising [55], would also occur in the context of strength exercise. This point is important to assess
 1142 to provide valid sonic interaction design recommendations in this case that concerns a large set of mobile applications
 1143
 1144

1145 for sport training. The fact that results found in arm raising might not simply be transferred to strength exercise is
1146 due to the attention focus during exercise being largely dependent on exercise intensity [41] and thus we cannot infer
1147 a priori that people would attend to the sound rather than their physiological sensations. Both our quantitative and
1148 qualitative findings do confirm the asymmetries in the sonification effects for ascending and descending sounds during
1149 squat exercises. Participants overall felt lighter, less tired, more capable, and motivated, and perceived the movement to
1150 be easier and felt more physically active with the ascending compared to the descending pitch sonification. Experiment
1151 2 showed that the feelings of lightness and flexibility induced by sound spread over the whole body (as opposed to a
1152 specific body part, such as in the case of vibration feedback). These effects may be linked to effects on proprioception
1153 and, ultimately, to the facilitation and enhancement of physical activity. In addition, we have extended the previous
1154 literature by investigating downward sonification accompanying not only upward movements but also downward
1155 movements. Indeed, no single study had previously measured the effects of the descending pitch sound in relation to a
1156 downwards movement, and based on previous studies [95, 97] it could not be assumed that the direction of the sound
1157 would have (or not) an effect on changes in body perceptions (we expand on this point in next sections). Asymmetries in
1158 the association of music parameters with movements have been found by [26], who report that “listeners who associate
1159 a musical stimulus with a particular kinetic quality often do not associate the inverse stimulus with the opposite kinetic
1160 quality”. Asymmetry in loudness perception variations for tones increasing or decreasing in pitch was also found by [88].
1161 First of all, our results showed that the incongruency between movement and sound direction was disliked, and that
1162 the congruency between movement and sound direction enhanced the sound induced body perception and experience
1163 quality. That is, the pairing of upward movement and sound was enhancing the positive sensation of lightness, speed,
1164 energy and positive mood induced by the upward sound. It also increased the perceived speed, the perceived sense of
1165 agency over the sound and it was perceived as helping in completing the squat. On the contrary, the pairing of the
1166 downward movement and sound was enhancing the feeling of heaviness, slowness and lack of energy. However, our
1167 results show also that, what may be perceived as a negative body feeling, may indeed be helpful in a strength downward
1168 movement. The feeling of being heavier provided a sense of facilitation in our participants as if the sound operated
1169 as a gravitational force. This is interesting for any strength downward movement where there is a conflict between
1170 the slowness of the movement due to movement control and muscle tension and the need for sense of progress (e.g.,
1171 returning from a pull-up bar movement, or downward phase of a plank exercise, or return of weighted arm raised
1172 exercise). Still, the effects generated by the interaction between the direction of the sound and of the movement are
1173 more complex as discussed in the following sections. Table 1 summarizes the design implications based on the effects
1174 observed in this study; we compare the effects with those observed for a light exercise, as reported in [55], as for that
1175 study the same sounds were used and movement behavior, body, movement and emotion feelings were also measured.

1184 7.1 Ascending Pitch is Perceived as More Positive than Descending Pitch Even in Strength Exercises

1186 The results from this research show that the ascending sound led to feelings of “springiness or bounciness” or being
1187 “pulled up”, which seem to be more prominent at the beginning of the movement, and which align with the qualitative
1188 reports of this sound in [57]. These observed effects relate to the effects of the cross-modal correspondence between
1189 pitch and vertical movement (e.g., [26, 51, 58, 104]) by which an ascending sound is associated with motion upwards,
1190 and may also affect the perceived body position, as suggested by [55, 97]. Such associations of tonal sounds rising
1191 in pitch have been also found in gestural depictions of sounds [53]. Moreover, the feelings of lightness and other
1192 PA-facilitation body feelings found for the ascending sounds also link to the bottom-up multisensory body-perception
1193 mechanisms by which enhancing the high-frequency of action sounds (i.e., footsteps sounds) lead to a perceived lighter
1194
1195
1196

Table 1. Body-effect sonification design framework with design implications based on the effects of directional sensory feedback observed in this study. Color indicates if effects on strength exercises were congruent (Green) or incongruent (Blue) with those observed in light exercises [55]. Gray background shows that the question had not been previously investigated

	Ascending sound Upwards movement	Descending sound Downwards movement	Ascending sound Downwards movement	Descending sound Upwards movement	Vibration congruent with movement direction
Experience quality	Energetic, excited, positive , correct	Negative, incorrect, enjoyed by some	Energetic, excited, positive, correct	Negative , incorrect	Excited
Body feelings	Light, less tired, capable, motivated, physically active	Heavy, tired, less capable, less motivated	Light, less tired, capable, motivated	Heavy, tired, less capable, less motivated	Flexible, strong
Body part affected	Whole body	-	-	-	Stimulated body part (here trunk)
Feelings of movement and proprioception	Fast, easy , useful	Slow, no energy	Fast, easy, useful	Slow	Fast, fluid
Behavior	Lower speed than no sound	Increased acceleration Lower speed than no sound	-	Increased acceleration	Lower speed than no sound
Guiding force	Lifted up, agency over sound, internal (self) force	Pushed down, internal (self) force	Reduced agency over sound	Reduced agency over sound	External force
Physical Activity Facilitation	Positive, facilitating	Facilitating	Positive, facilitating, but not preferred	Inhibiting, least preferred	-

body weight [91] and make people feeling more capable of exercising [95]. Like the ascending pitch squat sonification, the ‘high-frequency’ footsteps sounds whilst walking also significantly enhance emotional state, whereby the listeners feel more aroused and positive [91, 95]. Moreover, a recent study investigating the effect of manipulating the static pitch of classical piano excerpts found a positive association between pitch height and reported valence [45]. Thus, unlike the difference in the effect of static compared to dynamic pitch on physical size [27], the effect of static and dynamic pitch on valence and arousal seems to be rather similar. Previous research found that sound of lower frequency range can be perceived as less pleasant than sound with higher frequency range in specific contexts [45, 110]. This contrasts with our results, suggesting that the “metaphorical effect” of pitch change over-rule other direct effects. The reports of the qualitative experiences reveal positive-negative and success-failure contrasts between the two sonifications: participants commonly perceived the ascending pitch as the positive and the descending pitch as the negative sound. They also associated the ascending pitch with correctly performed movement and the negative descending sound with incorrect movement. Moreover, they perceived their body and movement more positively when their squat was accompanied by the ascending pitch, which led to positive reinforcement and encouragement to continue with the exercise, and more negatively with the descending pitch, which triggered feelings of failure and incorrectness and resulted in participants rejecting the sound and not taking ownership over it. In existing psychological literature, there is evidence of a metaphorical linkage between spatial elevation and various dimensions of experience and cognition. This includes the use of the ‘up’ and ‘down’ contrast to denote distinctions in positive and negative affect, as well as dominance and power dynamics [24, 62]. In prior works the connection between high/low pitch and high/low locations has also be explained partly through a more fundamental metaphorical association, where ‘down’ represents negativity and ‘up’ signifies positivity [22, 45]. Our study findings align with this metaphorical association, demonstrating that sounds descending in pitch (interpreted as descending to lower positions) were associated with failure or incorrectness, denoting negative contexts. Conversely, sounds ascending in pitch (interpreted as ascending to higher positions) were linked to positive contexts. Nevertheless, a more complex analysis is certainly needed. First, it remains to be established whether the triggered change in feelings and experience relate to the absolute frequency range of the sound ending, or

1249 more specifically to the direction of the pitch change, and the interaction between the loudness and pitch profiles that
1250 suggest different metaphors. Further investigations are needed to establish which sound parameters drive the association
1251 with certain metaphors, and if expectancy mechanisms created by the sound dynamics (pitch and/or loudness profiles)
1252 induce or favor specific movements [68, 69].
1253

1254 **7.2 Physical Demand of Exercise Shifts Attention to the Proprioceptive Feelings Triggered by the** 1255 **Directional Sound** 1256

1257 Our current results suggest that sonification directions (referring to increases/ decreases in pitch) may have different
1258 effects in demanding exercises from those observed for light exercise. They showed that the descending sonification
1259 increased the maximum acceleration of both the upward and downward movement directions. This contrasts with
1260 the reports from participants, who described the ascending sound as being, in addition to positive (see 7.1), energetic,
1261 empowering, stimulating, and awakening, energizing, and useful when trying to be more “explosive” (i.e., high-intensity,
1262 short-duration movement). Further, our results also contrast with those from previous literature on a simple upward
1263 arm raise movement [55]: in that study [55], higher acceleration was observed for the ascending vs. the descending
1264 sound. It is possible that the difference lies in the level of demand of the movement. For easy movements, the attentional
1265 focus may be on enjoying the experience, and then the positive and energetic feelings triggered by the ascending sound
1266 may have led to overdo and speedup the movement, while the negative feelings triggered by the descending sound may
1267 have reduced the motivation to perform the movement. Instead, the physical demand of the squat (or similar downward
1268 demanding movements) may have shifted the attention to the body, and then the proprioceptive feelings of slowness
1269 and heaviness triggered by the descending sound may have invoked a movement counteraction. In other words, the
1270 descending sound makes people feel heavier and slower, then people may feel the need to push their movements
1271 further to compensate for it and increase the speed and energy. This potential counteraction could explain the observed
1272 increase in maximum acceleration in both upward and downward movement directions in response to the descending
1273 sonification, which can be beneficial for some exercises such as explosive strength training. In supporting such an
1274 interpretation, in the descending-down pairing, while the feelings of heaviness were evoked, these were surprisingly
1275 seen as positively impacting the exercise, as this heaviness enhanced the perceived speed, quality, and amount of the
1276 downward movement, as if participants were being “pulled down” by the sound. This result is interesting as it shows
1277 how the effect of sonification on PA, modulated through dynamic body perceptions, not only depends on the form of the
1278 sound feedback but also on other internal factors that are critical in the specific activity or context. Previous literature
1279 had shown that the direction of changes in body size perception, and their physical activity facilitating/inhibiting
1280 effect, which were triggered by changes in frequency of footstep sounds, were affected by body-size related personal
1281 values. Those wanting to be heavier appreciated feeling heavier in response to the low frequency sound, while those
1282 wanting to be thin appreciated feeling lighter in response to the high frequency sound [95]. Our work adds to this
1283 literature by showing that not just internal body values but also demand of physical activity (with the shift in attention
1284 it may trigger: from emotional to proprioceptive sensation) modulates the responses to the same perceived body change.
1285 This interaction is also supported by Experiment 2 results suggesting that the effects may vary according to the level
1286 of fitness of the person and appear stronger in people with low fitness level. In particular, we found that while the
1287 minimally active group was more aware of the movement guidance provided by the sensory cues, such cues had a larger
1288 influence in the squatting movement quality (movement angle, time and velocity for the downward movement) of the
1289 inactive group. This interaction between focus of attention and effect of sound on behavior may be also supported by
1290 the Experiment 2 results where haptic feedback was used as a second control condition in addition to a more standard
1291
1292
1293
1294
1295
1296
1297
1298
1299
1300

1301 no-sound condition. The results of Experiment 2 show that while haptic feedback is perceived as an external force that
1302 helps the movement, sound is perceived as an internal force and possibly more easily associated with oneself and other
1303 internal processes. Indeed, sound was often considered more inviting to shift the attention from the body itself, while
1304 the haptic seems to bring back the attention to the specific body part stimulated. This is also clear from the fact that
1305 in Experiment 2, people associate haptic feedback with changes and sensations on the trunk whereas the sound was
1306 associated with a variety of body parts.
1307
1308

1309 7.3 Novelty and Contributions 1310

1311 Our work present significant contributions and novel insights regarding the impact of sound on movement facilitation
1312 and the associated sensory processes leading to changes in body perceptions, differentiating it from previous work in
1313 five key aspects:
1314

1315 **1. Nuanced Understanding of the Facilitation Effects of the Sound and Verticality Association on a Vertical**
1316 **Strength Exercise:** While the connection between sounds changing in pitch and the perception of verticality has been
1317 acknowledged in prior works [22, 27], and exploited in artistic practices [61] and rehabilitation [70], our research offers
1318 a deeper understanding in relation to exercise facilitation. We reveal a preference for ascending sounds concerning
1319 perceived success during exercise. Moreover, we highlight the unique benefits of both ascending and descending
1320 pitch sounds, contributing valuable insights for a broader understanding of their impact on body perceptions and on
1321 movement qualities during exercise performance.
1322

1323 **2. Comparative Analysis of Sound and Haptic Feedback:** While haptic feedback was included for comparative
1324 purposes, our study unveils distinctive sensory and motor processes associated with sound and vibration. We challenge
1325 the prevailing trend of utilizing vibration in commercial devices [19, 107], perhaps due to its social acceptability [20],
1326 suggesting that auditory feedback may offer advantages in sensory-motor learning [3], as sound is perceived as an
1327 internal force. This raises crucial questions regarding the extent to which haptic feedback truly facilitates motor learning
1328 compared to auditory feedback (see for instance works on the use of haptic feedback [111] or audiomotor feedback
1329 [30, 35] for motor learning). Our results suggest that audio might be more beneficial for self-connection during exercise,
1330 while haptic feedback may be more conducive to engaging with the external space. These findings shed new light on
1331 the design and utilization of feedback modalities for optimizing exercise experiences and motor learning.
1332
1333

1334 **3. Fitness-Level Dependent Effects and Body Perception:** A distinctive contribution of our study is the observa-
1335 tion that the effects of sound on movement facilitation may vary based on an individual's fitness level, exhibiting greater
1336 or impact in individuals with lower fitness levels. This was already suggested by a prior qualitative study [57], but our
1337 study provides experimental evidence for it. This insight introduces new prospects for effectively supporting individuals
1338 who face challenges in engaging with physical activity. Moreover, this contribution enriches the existing literature on
1339 the multifaceted factors that influence body perception, incorporating physical activity level as a significant determinant
1340 alongside already recognized personal values [95]. By delineating how fitness levels interact with sound-induced effects
1341 on movement, our research enhances the understanding of the complex interplay between body perception and physical
1342 activity engagement.
1343
1344

1345 Further, while not a novelty originating from this study specifically but rather stemming from recent research, we wish
1346 to emphasize our **perception-centric approach to exercise**. This diverges from prior research exploiting cognitive
1347 behavioral therapies [40, 76, 108]. Rather than centering on reward-based or goal-oriented behavioral strategies, our
1348 study aligns with a complementary approach proposed in recent studies [57, 91], which focuses on how individuals
1349 perceive themselves and their bodily movements **during the moment of** exercise.
1350
1351

1353 **4. Use of Sound for Enhancing VR and Game Experience:** Our findings contribute to other domains by providing
1354 further understanding on how sound could be exploited to alter people’s experience of their body and movement. For
1355 example, the findings from our studies open new opportunities for game scenarios that involve vertical body movements.
1356 Large or demanding vertical body displacement in games has been addressed by physically lifting a person using ropes
1357 attached to large infrastructures, which require large spaces [49, 103], or using heavy wearable propellers [78, 100],
1358 limiting the person’s movement. A more viable solution has been recently proposed by [71]. They alter the perception
1359 of the height of a vertical displacement by moving a weight up and down along the user’s back. The movement of
1360 the weight alters the perceived jump momentum, creating the sensation of a more accelerated or decelerated vertical
1361 jump. In addition, they show that such an approach reinforces the visual illusion when used in VR. Unfortunately, such
1362 solution requires a person to wear a large backpack. Our findings suggest that this illusion could be modulated by
1363 simply altering the sonification of a person’s vertical displacement. Furthermore, as shown in [71], the combination of
1364 downward and upward sonification congruent or incongruent to the vertical displacement, could enable the creation of
1365 various modulations, making the vertical displacement feel easier or more demanding (creating an illusion of resistance)
1366 as required. The impact itself could be also manipulated by altering the ending of the sonification (e.g., slowing it down,
1367 or interrupting it abruptly) to alter the feeling of the terrain material [8] and its interaction with the body weight. It
1368 remains however to investigate the amount of illusion displacement that the sound would be able to generate alone or
1369 in combination with other congruent sensory feedback.

1374 **5. Leveraging Sonification for Strategic Congruence and Incongruence to Shape Body-Movement Associa-**
1375 **tions:** In addition, this work contributes to the body of literature on sensory incongruence [63, 101]. A synthesis of
1376 the literature on the use of sensory alignment from various disciplines in the area of entertainment technology [60]
1377 suggested that audio interacting with kinaesthetic experience appears to only enhance the sense of body rotation. Our
1378 findings suggest that carefully designed movement sonification could offer additional opportunities to enhance or
1379 alter the virtual reality kinaesthetic experience by altering the perceived body weight and augmenting the sense of
1380 success or failure. In terms of incongruence between sensory stimuli, Kim et al. [48] found that semantic incongruence
1381 between audio and visual feedback did not lead to a negative effect. Instead, it created a novelty effect. The authors
1382 argue that this difference from previous studies on sensory incongruence was due to the audio representing aspects of
1383 the environment only, and not of the person-avatar. In our study, the incongruence introduced by sound was spatial
1384 and related to one’s body. A possible explanation for the acceptance of the illusion could be that the sonification was
1385 not a natural sensory experience that one would normally encounter when moving (such as it would be in for footsteps
1386 sounds [96]). Hence, we argue that people were able to attribute meaning to the incongruence between the sound and
1387 the different aspects of their body and movement, allowing them to make sense of it in that way. They attributed the
1388 incongruence in direction between the movement and the sound to the weight of the body rather than the movement
1389 direction, using this link to guide their meaning-making process and evaluation of the experience. This was enabled by
1390 the fact that the temporal alignment was maintained to ensure agency [63], enabling spatial and metaphorical/semantic
1391 associations to take place. One could argue, therefore, that the congruence and incongruence of sonification with the
1392 movement could be carefully designed to trigger associations with the movement or other aspects of the body that may
1393 influence movement to reach the desired experiential outcome.

1400 7.4 Limitations and Future Research

1401 **7.4.1 Generalizability.** A limitation regarding generalizability of this study, like many others in the field (e.g. [55, 68, 69,
1402 81, 83]), is the focus on one particular exercise (in our case, a strength exercise: squats). While each individual focused
1403

1405 study like ours is not able to make generalizable claims about physical activity in general, they add to the earlier body
1406 of work, putting to test, but also build on, and extend on designs (e.g., different sonifications), application (e.g., different
1407 physical exercises), and insights in those earlier studies. Hence the growing body of focused studies like ours allow for
1408 a growing understanding of the interaction between sound and movement behaviour, body perception, and experience
1409 quality in physical activity. Yet, further work is needed to test our findings to other body movements and types of
1410 exercises in order to generalize our findings. In particular future squat sonification designs should be evaluated both
1411 with regard to their short- as well as long-term effects in the context of physical activity participation. Further, as the
1412 focus of our paper was on building on understanding the experience quality of participants, we measured emotional
1413 responses with affective reports; body perceptions were measured in terms of body feelings and impact on movement
1414 behavior. Because emotional and body feelings are subjective, to have a full understanding of how emotional state and
1415 body-perception were affected by the use of our device, future studies could investigate the effects on physiological
1416 reactivity and other overt behavioral acts apart from the body movement features explored in this study.

1420 Finally, a decision was made to solely include women as participants in order to mitigate potential confounding
1421 factors arising from physiological differences. Consequently, our findings from this study can only be extrapolated
1422 to this specific population and are not completely generalizable. As a next course of action, we plan to widen the
1423 recruitment criteria and delve deeper into the impact and interactions of these variables in relation to sonification
1424 effects.

1426 **7.4.2 Methodology.** Technical issues were exacerbated due to methodological complications imposed by COVID-19. In
1427 particular, the experimental application used in Experiment 1 needed to be deployed remotely in different environments,
1428 on different smartphones and software versions with no researcher support to position the phone on the body or
1429 troubleshoot the application. In some smartphone models, participants reported a slight sonification lag, especially
1430 during the upward movement. This technical issue is likely due to the audio latency of specific smartphone models.
1431 Delays between action and sensory feedback can disrupt the agency and diminish the saliency of the sensory-induced
1432 bodily illusions [96], as reported in some cases in this study. This adverse delay was minimized in Experiment 2, which
1433 ran in a lab setting with the support of a collocated researcher. Still, some participants reported delays in sound and
1434 vibration in line with their movement, which was due to rapid launch of squats (i.e., in those cases the reported issue was
1435 not due to latency but to the duration of sound and vibration stimuli being longer than the time required to complete
1436 the squats). Experiment 2 only included women as participants. Future work would require including more diverse
1437 participants with regards to gender as well as other aspects (e.g., fitness level, age, body ideals). With respect to tools
1438 used in this experimental design, in retrospect we realized the body outlines used in this study portrayed an exaggerated
1439 and far from common idealized female body, which could potentially have an opposite effect in the population than
1440 the tool intended, i.e. feeling not well represented, or even excluded [85]. Hence we encourage researchers employing
1441 Body Maps to employ more inclusive empty outlines, better representing the plurality of bodies the design or research
1442 targets [85].

1448 **7.4.3 Sonification Design.** Also related to a methodological limitation, in Experiment 2, we chose the haptics modality as
1449 the second control condition to trigger comparative reflections in people and help them make explicit their experiences,
1450 but a direct comparison of the effects was not intended. Nevertheless, the vibration feedback emerged to be interesting
1451 on its own. Recent works have shown the potential of haptic metaphors delivered to the body to elicit changes in bodily
1452 feelings (feeling heavy, strong) [98] and facilitate physical activity through such body-perception changes [52, 93].
1453 These results together invite more research on haptics for body perception changes in physical activity. Moreover, the
1454

1457 present study used sounds and vibrotactile sequences of a fixed duration (i.e., 1300 ms). We found that the temporal
1458 alignment between the squat sonification onset as well as its progression and the actual movement is important to
1459 ensure a sense of agency and saliency of evoked bodily experiences; for instance, to avoid misalignment between
1460 stimulus and movement in the case of rapid squats. Because of this, an anchoring approach [76], whereby small
1461 pieces of the sonification are played at each movement stage (i.e., discrete sonification), could strengthen the mental
1462 association between the movement and the sound. Given that the most salient and enjoyable experience evoked by the
1463 squatting movement sonification was the spring-like or bouncy-ball sensation, future squat sonifications could explore
1464 more metaphorically-aligned sound-movement pairings [56]. Hence, using spring-like or bouncy ball sounds instead
1465 of the musical sounds for the squatting movement sonification might enhance the reported facilitatory spring-like
1466 sensations as well as the saliency of other auditory bodily illusions. These sounds could still incorporate the pitch
1467 change and by doing so not only facilitate the reported changes in body feelings, but also enhance the sense of agency:
1468 as shown by qualitative reports, the ascending-up pairing was perceived as the most synergetic and in-sync with one's
1469 movement, resulting in a higher perceived sense of agency over the sound. On the contrary, participants reported that
1470 the descending sound led them to reject it as being produced by them, in order to minimize the negative association
1471 between this sound and feelings of failure and incorrectness.
1472
1473
1474
1475
1476
1477

1478 8 CONCLUSION

1479 Previous works have shown that sounds ascending in pitch accompanying a simple movement create a sense of lightness
1480 and ease, accelerate movement and trigger positive feelings, while sounds descending in pitch create a sense of heaviness
1481 and slowness. Here we investigated whether these effects extend to an exercise requiring larger effort and tested for the
1482 first time the interaction between sound direction and movement direction. Our study provides valuable and unique
1483 insights into the influence of sound on movement facilitation and body perceptions during exercise, distinguishing itself
1484 from prior research by addressing three critical aspects: a nuanced understanding of sound and verticality association,
1485 a comparative analysis of sound and haptic feedback, and the identification of fitness-level dependent effects on body
1486 perception during physical activity. In particular, our results show that independently of the movement direction, the
1487 ascending pitch sound triggers feelings of being lighter, less tired and more capable, while the descending pitch triggers
1488 feelings of being heavier, even in a more demanding exercise. Extending previous results, we show that the congruence
1489 between the direction of the movement and the direction of the sound amplifies the related effects. In addition, our
1490 work shows that the different elicited body and experience quality by both ascending and descending sounds support
1491 movement and physical activity in different ways, in particular because the increase in the physical demand of exercise
1492 seems to shift the focus of attention from the positive or negative feelings to the proprioceptive feelings triggered by the
1493 sound. Finally, we show that sound feedback generates an internalized force that guides and helps to perform squats,
1494 specially inactive people. Our results open opportunities for supporting physical activity in demanding situations
1495 through wearable devices incorporating sonification of movement using musical sounds changing in pitch. While we
1496 have focused on one exercise only, squat, its physical demand, complexity in terms of demand on various body parts and
1497 its complementarity with literature on an arm raise exercise provide insights on possible effects on a variety of vertical
1498 displacement strength exercises. Transfer of effects to other strength vertical exercises (e.g., jump-squat, cube-step,
1499 weight lifting, plank, pull-up bar) is also supported by the similarity in results observed on the facilitation and positive
1500 effects of the ascending sound on the ascending direction of the movement despite the strength demand.
