10 AI regulations are expected to prohibit machine learning models from using sensitive attributes during training. However, the latest Natural Language Processing (NLP) classifiers, which rely on deep learning, 11 operate as black-box systems, complicating the detection and remediation of such misuse. Traditional bias 12 mitigation methods in NLP aim for comparable performance across different groups based on attributes 13 like gender or race but fail to address the underlying issue of reliance on protected attributes. To partly 14 fix that, we introduce NLPGUARD, a framework for mitigating the reliance on protected attributes in NLP 15 classifiers. NLPGUARD takes an unlabeled dataset, an existing NLP classifier, and its training data as in-16 put, producing a modified training dataset that significantly reduces dependence on protected attributes 17 without compromising accuracy. NLPGUARD is applied to three classification tasks: identifying toxic lan-18 guage, sentiment analysis, and occupation classification. Our evaluation shows that current NLP classifiers 19 heavily depend on protected attributes, with up to 23% of the most predictive words associated with these at-20 tributes. However, NLPGUARD effectively reduces this reliance by up to 79%, while slightly improving accuracy. 21

1 INTRODUCTION

In recent years, the adoption of deep learning-based NLP models has exponentially increased. Transformer-based models, such as BERT [18], T5 [57], and GPT [8], have achieved unthinkable levels of performance on several natural language tasks. However, despite being increasingly accurate, these models remain black-boxes [28]. For an NLP classification task, models predict a class label from an input text without providing any information on the complex internal decisionmaking mechanism, making it challenging to identify and mitigate potential bias and/or unfair behavior in such models.

ification of the four sentences in Table 1. The more intense the red (blue) color of a word, the more important the word contributes to toxic (non-toxic) classification.

Upcoming privacy laws regulating the use of AI will soon demand that learning shall not be 61 done on protected attributes such as race, gender, or sexual orientation, as already identified by 62 the General Data Protection Regulation (GDPR), the UK Government, and the anti-discrimination 63 legislation in the United States [10, 21, 26]. Ensuring AI models avoid using protected attributes in 64 decision-making is termed 'fairness through unawareness' [45], and it is crucial in many real-world 65 scenarios. For instance, NLP-based systems often assess job applicants' resumes. Following the Civil 66 Rights Act in the US, discrimination based on race, sex, nationality, or other protected attributes is 67 forbidden. Hence, these NLP systems must omit words linked to protected attributes to prevent 68 discriminatory practices against candidates, such as the "sexist" Amazon Recruitment tool,¹ a 69 system that learned to downgrade resumes containing the word 'women'. Content moderation is 70 another example, where all users should be treated equitably, without having their contributions 71 censored or suppressed because of, for example, their demographic characteristics. 72

However, as we will demonstrate in our analysis, state-of-the-art models often base their pre-73 dictions on protected attributes, and accurate ones are frequently black boxes, posing challenges 74 in identifying such misuse. Consider, for example, the task of determining whether a sentence 75 contains toxic language or not in a dataset we will analyze. In Figure 1, we report four example 76 sentences, together with the outcome of a toxicity classifier P(T); in Figure 2, we highlight in red 77 the important words used by the classifier to make these predictions. As shown, the presence of 78 words such as 'black', 'gay', or 'homosexual' is used to distinguish between toxic or non-toxic texts. 79 Yet, these words are protected attributes and should not be used in such classifications at all. 80

As discussed in §2, prior studies on bias in NLP primarily focused on two challenges: ensuring fair 81 performance across different groups and rectifying unfairness in word representations. However, 82 these solutions only target specific biases and fail to eliminate the reliance of models on protected 83 attributes for predictions. Therefore, we propose methods to reduce this bias in black-box NLP clas-84 sifiers, removing most protected attributes from their decision-making process while maintaining 85 accuracy, and making these approaches applicable across various datasets and tasks. 86

In so doing, we make four main contributions:

- (1) We introduce NLPGUARD (§3), a framework with three components: (1) an Explainer that finds the most important words for predictions; (2) an Identifier that checks if these words are about protected attributes; and (3) a Moderator that adjusts the training data to re-train the NLP model to reduce learning from such protected attributes.
- (2) We evaluate each part of our framework and use it to mitigate toxicity detection in Wikipedia comments with BERT (§4). BERT depends on protected attributes for toxicity predictions (23% of the most predictive words), but our approach cuts this down by 60% and even increases prediction accuracy by 0.8%.

¹https://www.bbc.com/news/technology-45809919 97

- (3) We then evaluate whether our framework generalizes to different types of data and tasks,
 not just toxicity detection (§5). We found that our framework reduces the use of protected attributes by 79% when applied to out-of-distribution data. Also, it reduced reliance on protected attributes without compromising accuracy in tasks like sentiment analysis and occupation classification.
 - (4) We make NLPGUARD publicly accessible,² and discuss how to incorporate it into existing NLP systems, its impact, and its limitations (§6).

105

108 2.1 AI Regulations and Laws

109 The growth of AI systems has raised privacy and discrimination concerns, leading to the introduction 110 of numerous regulations and laws governing their use. In the European Union (EU), in May 2018, 111 the GDPR [70] was introduced, which demands organizations ensure that personal data is processed 112 lawfully, fairly, and transparently. It prohibits processing sensitive personal attributes such as race, 113 ethnicity, religion, and political opinions, unless legitimately justified. The EU proposed the AI 114 Act [42, 71], which defines rules and obligations depending on the level of risk of AI systems (e.g., 115 transparency, documentation, human oversight) [51]. In the United Kingdom (UK), the UK Equality 116 Act 2010 [35] established that it is unlawful to discriminate based on nine protected characteristics: 117 age, disability, gender reassignment, marriage and civil partnership, pregnancy and maternity, 118 race, religion or belief, sex, and sexual orientation. Compliance with the act is enforced by the 119 Equality and Human Rights Commission (EHRC). In the United States (US), the Anti-discrimination 120 Act [12] safeguards individuals from unfair treatment based on protected attributes. In late 2022, 121 a blueprint of the AI Bill of Rights was passed [32], declaring that algorithms that discriminate 122 or perform unjustified different treatment based on protected attributes violate legal protections. 123 AI regulations will continue to evolve in the coming years [34, 49], driven by a common goal: to 124 minimize discriminatory outputs based on protected characteristics [10, 21, 26]. 125

¹²⁶ 2.2 Bias mitigation for NLP

Bias in NLP decision-making has manifested itself in several ways, including dialogue generaBias in NLP decision-making has manifested itself in several ways, including dialogue generation [19], text classification [20], and machine translation [66]. It usually arises from training data
[22, 67]. For instance, pre-trained models and word embedding can inherit biases and stereotypes
present in the large training corpora [7, 9, 25, 58]. When quantifying bias, existing works generally
highlight disparities between demographic groups, with differences in performance or selection
bias on protected attributes such as race, gender, religion, and sexual orientation [22, 29, 37, 67].

133 To address biases in NLP, techniques can be developed that act at the three main stages of the 134 NLP pipeline [38, 75]: pre-processing (modifying training data), in-processing (imposing fairness 135 constraints during model training), and post-processing (adjusting classifier predictions based on 136 fairness metrics). Most existing works focus on the first two stages, exploiting data augmentation 137 and modified model training techniques [4, 6, 20, 52, 58, 64, 77]. Furthermore, most of those 138 studies focus on one protected category at a time. For example, Badjatiya et al. [6] proposed the 139 identification of protected attributes, such as gender, by creating a manual list of words, measuring 140 the skewed occurrence of words across classes or predicted class probability distribution of words. 141 Park et al. [52] introduced gender swapping to equalize the number of male and female entities in 142 the training data. Dixon et al. [20] proposed dataset augmentation strategies that generate new 143 sentences using templates or replace protected attributes with generic tags, such as part-of-speech 144 or named-entity tags. Zhang et al. [77] proposed mitigating biases in the training data by assuming 145

²The code repository of our framework is available at https://github.com/grecosalvatore/nlpguard

a non-discrimination distribution and then reconstructing the distribution using instance weighting.
 Ravfogel et al. [58] proposed removing information from neural representations concerning gender
 or race for debiasing word embedding for NLP classification.

These past works try to mitigate unintended bias and performance imbalance between subgroups 151 by (1) removing implicit bias from word embeddings, (2) performing data augmentation on the 152 training set (data-based), or (3) intervening directly in the model architecture or objective function 153 (model-based). However, a gap remains in evaluating (and tackling) the extent to which NLP 154 155 classifiers depend on protected attributes for their predictions. In this paper, we aim to fill that gap. We consider the following definition of fairness through unawareness: "an algorithm is fair as long as 156 any protected attributes are not explicitly used in the decision-making process" [27, 40, 45]. Textual 157 data is unstructured; hence, protected attributes are not explicitly delineated as input features, 158 such as columns used in structured datasets. Consequently, we refine this definition in the context 159 of NLP applications to ensure words associated with protected characteristics are not utilized in 160 decision-making unless necessary. Our approach aims to reduce the use of protected attributes in 161 the decision-making process of NLP models, thereby better aligning them with legal regulations. 162

Compared to prior work, our approach not only has a different objective, but it also overcomes two 163 of their main limitations: (1) their focus on a subset of protected attributes at a time (usually race and 164 gender); (2) their manual and static identification of protected attributes via pre-defined dictionaries, 165 lists of identity terms, or additional annotations. The only technique addressing these limitations is 166 Entropy-based Attention Regulation (EAR) [4]. EAR introduces a regularization term to discourage 167 overfitting to training-specific potentially biased terms. However, those terms are automatically 168 identified during training, leaving no flexibility for users to select which categories to mitigate. 169 Unlike previous techniques, our approach: (1) identifies and mitigates multiple protected categories 170 simultaneously; (2) can be fully automated, allowing for a dynamic update of the dictionary of 171 protected attributes; and (3) allows for the selection of the categories to mitigate. 172

173 174

3 OUR MITIGATION FRAMEWORK

175 Our Mitigation Framework, namely NLPGUARD, has been designed to be generally applicable to any 176 supervised machine learning-based NLP classification model applied on an unlabelled corpus. As 177 illustrated in Figure 3, NLPGUARD takes in input an unlabeled corpus and a pre-trained NLP classifier 178 (together with its training dataset) to produce a mitigated training dataset in output. Ground truth 179 class labels for the unlabelled corpus are not required; rather, the classifier is used to generate them, 180 both for in-distribution (i.e., data that comes from the same distribution as the original training 181 dataset) and for out-of-distribution data where labels are unavailable. Because of the black-box 182 nature of NLP classifiers based on deep learning models, labels might be predicted using protected 183 attributes. To mitigate that, our framework comprises the following three components: 184

A. Explainer. This component uses Explainable Artificial Intelligence (XAI) techniques to identify 185 the most important words used by the model for its predictions. The XAI field has made great 186 strides in making black-box models more transparent, and several techniques exist to explain NLP 187 classifiers [14]. The best one for our purpose should have two qualities: (1) quantify the importance 188 of each feature word (feature-based), and (2) be applicable to explain the model's predictions after 189 training (post-hoc). Many techniques meet these requirements, and most of them measure the 190 importance of each word for the prediction within an individual sentence (local-explanations) 191 [2, 44, 59, 63, 69, 73]. Our Explainer component first identifies the words important for prediction 192 within all individual sentences, exploiting any of those techniques. Each word is, as such, associated 193 with multiple scores, one for each occurrence in each sentence. Second, it determines the most 194 important predictive words for the model as a whole (global-explanations) following the idea of 195

A Framework for Mitigating the Use of Protected Attributes

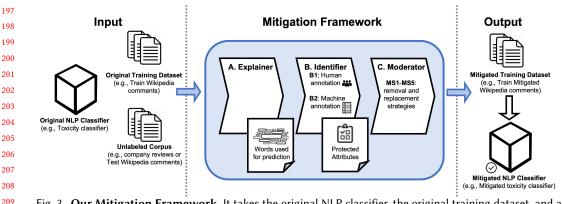

Fig. 3. **Our Mitigation Framework.** It takes the original NLP classifier, the original training dataset, and a new unlabeled corpus as input. The framework consists of three components: A) an *Explainer* that identifies the most important words used by the classifier for predictions on the unlabeled corpus; B) an *Identifier* that determines which of those words are protected attributes; and C) a *Moderator* that generates a mitigated training dataset to re-train the classifier so to reduce reliance on the previously identified protected attributes.

some of these techniques, which aggregate the words' importance over many sentences to compute the overall importance [72, 73]. Specifically, for each word, it sums all their individual scores and divides them by their frequency to compute the word's classification score. The normalization step is required to also identify rare but important words. The output of the *Explainer* component is the ordered list of the most important words for the model's predictions.

B. Identifier. This component aims to annotate which of the previously detected important words refer to protected attributes. We consider the nine protected categories defined by the Equality Act: *age, disability, gender reassignment, marriage and civil partnership, pregnancy and maternity, race, religion or belief, sex,* and *sexual orientation.* Our framework allows for annotation using *human-in-the-loop* (B1) and *machine-in-the-loop* (B2) approaches.

B1. Human-in-the-loop Annotation. Crowdsourcing platforms, such as Amazon Mechanical Turk (MTurk) and Prolific [13], have been extensively used by the research community to recruit crowdworkers for data labeling purposes. Crowdworkers [60, 68] are anonymous people usually paid for completing simple tasks. This component leverages crowdsourcing to perform the protected attribute annotation of the most important words. In our work, we exploited MTurk, where for each important word {worD}, participants were asked to answer the following question:

Question: Is the word {word} referring to:

Possible Answers: 1. Age, 2. Disability, 3. Gender reassignment, 4. Marriage and civil partnership, 5. Pregnancy and maternity, 6. Race, 7. Religion or belief, 8. Sex, 9. Sexual orientation, 10. None of the above;

To ensure data quality, we adopt a trap mechanism to detect random responses from participants and reject them (details of this mechanism are presented in §4.3).

B2. Machine-in-the-loop Annotation. As a cost-effective and scalable alternative to human-in-the-loop annotations via crowdsourcing, we also implemented a protected attributes annotation process that uses Large Language Models (LLMs). We did so inspired by a recent study [23] that found LLMs, including ChatGPT, to outperform crowdworkers in text-based annotation tasks. It also has been shown that LLMs are effective in solving many NLP tasks [56]. Specifically, we implemented an annotation process that interacts with ChatGPT as follows: two prompts provide the protected categories, their definitions, and links with additional information. Then, for each word, the LLM is asked to: (1) classify the word into one of the protected categories or none of them;

(2) provide a reliability score in the range [0, 100]; and (3) provide an explanation. For example, the
word *'homosexual'* would be classified with the protected category *sexual orientation* and a score of
100/100 by GPT-3.5-Turbo (see Figures 6 – 9 in Appendix A for further details).

C. Moderator. This component produces a new mitigated training dataset that can be used to train a new classifier that uses fewer protected attributes previously identified. It takes the original pre-trained classifier, the original training dataset, and the list of the most important words enriched with the protected attribute label as input. It produces a new *mitigated training dataset* by adjusting the training dataset based on the identified protected attributes that can then be used to train a new mitigated classifier. We designed and tested five mitigation strategies (MS).

(MS1) Sentence-level removal. Previous works have shown that subsampling can be an easy but effective technique for data balancing [33, 61]. This mitigation strategy eliminates all sentences containing protected attributes from the training set. As a result, it reduces the overall number of training examples. For example, if a word W_i is identified as a protected attribute, all sentences in the training set that include that word are removed. The idea behind this strategy is that the imbalance in the number of training examples containing protected attributes for a particular class may have led the model to learn that these protected attributes are crucial for classifying that class.

(MS2) Word-level removal. This strategy removes only the protected attribute words from the sentences in the training set while preserving the number of examples. The process involves removing the identified protected attribute words from all sentences in the training set, thereby removing their influence on the model's learning process. The idea is that the model should be able to classify sentences without relying solely on the protected words, and rather use other words in the text too.

(MS3) Word-level replacement with a random synonym. This strategy replaces every 269 instance of a protected attribute in the training set with one of its synonyms. It first uses embedding 270 similarity techniques to identify the k-nearest neighbors for each protected attribute. Then, it 271 randomly selects one of the k-most similar words to replace each instance of the protected attribute 272 in the training set. This has been shown to mitigate bias in [6], and it is believed that it may also 273 help mitigate the use of protected attributes in classification, as the model may learn to rely on other 274 words for classifying the classes rather than solely relying on protected attributes. This approach 275 maintains the same number of examples in the training set but increases the diversity of words. 276

(MS4) Word-level replacement with K random synonyms. This strategy expands the training set by generating new sentences using synonyms of protected attributes. Instead of replacing the protected attribute in-place with one similar word as in MS3, it creates k new sentences by replacing the protected attribute with each of its k-nearest neighbors. For example, given a sentence containing a protected attribute W_i , k new sentences are created by replacing W_i with each of its k most similar words. This increases the size of the training set and diversifies the words used in the sentences.

(MS5) Word-level replacement with hypernym. This strategy replaces instances of protected attributes in the training set with higher-level words, called hypernyms, which provide a more general representation of the category to which the protected attribute belongs. For example, the hypernym of 'dog' could be 'animal'. By using hypernyms instead of the specific protected attributes, the model may not discriminate based on these attributes in its classifications. This technique has been shown to be effective in mitigating accuracy imbalance between subgroups [6].

4 FRAMEWORK EVALUATION: EFFECTIVENESS AND SENSITIVITY

We evaluate the effectiveness of our framework and the sensitivity of the *Explainer* (§4.2), *Identifier* (§4.3), and *Moderator* (§4.4) components in mitigating a toxicity classifier applied to in-distribution data (i.e., the test set).

295 4.1 Evaluation task

We choose toxicity prediction as the main evaluation task in line with previous research. Toxicity classifiers are used in different contexts [39, 76], such as Reddit, Twitter, and 4chan, with competitive performance. However, they suffer from different types of biases [15, 16, 31, 62]. In Wikipedia, for example, any comment containing words associated with insults, offense, or profanity, regardless of the tone, the intent, and the context, would be classified as toxic; toxic language was however more likely predicted from minority communities, as found in [15], thus suggesting the use of protected attributes by such models.

In our experiments, we used the "original model" in the widely used detoxify [30] library³ as a pre-trained toxicity classifier. This is a BERT-base and uncased model [18] trained on a dataset of publicly available Wikipedia comments.⁴ It was fine-tuned for predicting 6 labels related to toxicity: *toxicity, severe toxicity, obscene, threat, insult,* and *identitiy attack,* achieving an average Area Under the ROC Curve (*AUC*) score of 98.6%. For the *toxicity* label only, the classifier achieved 0.82 macro and 0.93 weighted F1 scores (the dataset is imbalanced). This classifier is applied to the original test set comprising 153,164 texts, and predicted the toxicity label for 36,148 texts (23.6% of the test set).⁵

4.2 Component evaluation: Explainer

The *Explainer* aims to identify the most crucial words utilized by the classifier for predictions (as described in §3-A). The employed XAI technique can influence the words recognized as significant, thereby impacting the identified protected attributes on which the model relies to make predictions.

4.2.1 Evaluation metrics. To evaluate the effectiveness of the Explainer component, we first measure 316 the impact on the model's predictive performance (F1 score) by removing the most important words 317 identified by each XAI technique. An effective and precise explainer should result in a noticeable 318 decrease in the predictive performance when these words are removed. Secondly, to assess the 319 sensitivity of the *Explainer*, we measure the overlap of the most important words identified by 320 different XAI techniques. A substantial overlap indicates consistent outputs across XAI techniques. 321 Lastly, we measure the computation time for generating explanations to assess the efficiency of the 322 *Explainer* based on the XAI technique, which is a crucial aspect when dealing with large datasets. 323

324 4.2.2 *Explainer setup.* There are two main categories of XAI techniques to compute explanations 325 within a sentence: permutation-based and gradient-based [14]. For this comparison, we instantiated 326 the Explainer component with SHapley Additive exPlanations (SHAP) [44] as a representative of the 327 permutation-based and with Integrated Gradients (IG) [69] of the gradient-based techniques. Both 328 techniques have demonstrated competitive performance in prior studies [3]. Specifically, for SHAP, 329 we used the *text permutation explainer* with 3,000 as the maximum evaluation step parameter. For 330 Integrated Gradients, we exploited the implementation provided by the Ferret [5] library. 331

4.2.3 *Results.* We produced the explanations within each sentence over the toxic texts in the test 332 set using both techniques (SHAP and IG); we then aggregated individual scores and extracted an 333 ordered list of the most toxic words as previously described in §3-A. Figure 4 shows the decrease 334 in the F1 score by removing the most important words in the range [50, 700] with a step of 50. 335 As expected, removing the most important words from the test set causes a marked decrease in 336 predictive performance, especially for the top 250 words. IG exhibits higher precision, leading to 337 a more substantial decrease initially. However, the decrement tends to converge on the top 400 338 words for both techniques. This shows that both techniques effectively extract the words used by 339

³⁴¹ ⁴https://www.kaggle.com/competitions/jigsaw-toxic-comment-classification-challenge/data

³⁴² ⁵The ground truth labels are available only for a subset of the test set (42%).

³⁴⁰ ³https://github.com/unitaryai/detoxify

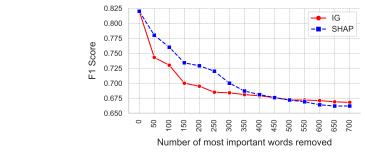

Fig. 4. **Explainer component evaluation.** F1 score decrease by removing the most important words from the test set, extracted by the *Explainer* component with Integrated Gradients (IG) and SHAP techniques. A greater decrease indicates a higher precision in identifying the most important words for predictions.

the classifier for its predictions. We selected the top 400 most toxic words (approximately 10%) – removing additional words caused a lower decrease in predictive performance.

We then measured the overlap between the 400 most toxic words identified with IG and SHAP. We found that 307 out of the 400 words were identical (77%), indicating a substantial agreement between the two techniques. The 23% of disagreement may be attributable to the varying precision levels inherent in the two methods.

Finally, we compared the execution times required to generate explanations using both techniques. We observed that IG significantly outperformed SHAP, completing the explanation process more than two orders of magnitude faster. On average, the execution time in seconds to obtain an explanation is approximately 0.2 for IG and 30 for SHAP, using a single Nvidia RTX A6000 GPU.

In summary, Integrated Gradients proves to be the most effective technique for the *Explainer* component, as it exhibits higher precision in identifying the most crucial words and executes significantly faster. As a result, we adopt Integrated Gradients in the *Explainer* for all subsequent experiments. Nevertheless, the framework allows the use of alternative XAI techniques.

4.3 Component evaluation: Identifier

The *Identifier* aims to determine which of the most important words are actually protected attributes (§3-B). To evaluate its effectiveness, we compare the protected attributes identified by the component instantiated with human-in-the-loop and machine-in-the-loop approaches against the annotations provided by two expert annotators, who possess a greater depth of knowledge of the definitions of protected categories by AI regulators than participants engaged in the human study.⁶ We also add for comparison a pre-defined dictionary of 51 protected attributes from previous works [6, 20].

4.3.1 Evaluation metrics. We measure the Cohen's kappa inter-annotator agreement [11] to evaluate the accuracy and reliability of the protected attributes identified by the different approaches. It ranges between [0, 1]; the higher the score is, the higher the agreement.

4.3.2 Protected attributes identifier setup. We selected the 400 most toxic words extracted with
 the *Explainer* component instantiated with Integrated Gradients as the candidate set to identify
 protected attributes. Then, we configured the *Identifier* as follows.

 ⁶Expert annotators are people within our team with a background in human-computer interaction and trustworthy and
 responsible AI. They are located in two different Western countries, with different ethnicities and ages. They carefully read
 the UK Equality Act 2010 and unanimously agreed on the annotation to be performed, which was done independently.

	A1	A2	GPT	МT	D
A1	1	0.81	0.67	0.48	0.19
A2	0.81	1	0.56	0.44	0.21
GPT	0.67	0.56	1	0.54	0.14
μ	0.48	0.44	0.54	1	0.12
□ -	0.19	0.21	0.14	0.12	1

Fig. 5. **Identifier component evaluation.** Cohen's kappa annotator agreement in labeling protected attributes for the 400 most toxic words. The annotation was performed by two expert annotators (A1 and A2), ChatGPT (GPT), MTurk (MT), and a pre-defined dictionary (D). The two-by-two Cohen's kappa annotator agreement is reported, in the range [0, 1], where a higher score indicates a higher level of agreement.

Human-in-the-loop setup. We set up an MTurk study where we asked annotators to label words with the protected category they refer to (if any). As anticipated in §3-B1, we also used a trap mechanism to detect poor quality responses; specifically, we gave annotators the following definition of toxicity: *"Toxic language is a way of communicating that harms other people"*. Then, for each word, we also asked participants to answer the following additional trap question:

Trap Question: Does the word *{WORD}* suggest toxic language? **Possible Answers:** 1. Not at all, 2. Very little, 3. Somewhat, 4. To a great extent, 5. Definitely.

416 To the list of 400 most toxic words, we added 15 trap words that can be easily classified as toxic 417 (e.g., "asshole") or *non-toxic* (e.g., "friendly"). The full list of trap words can be found in Table 5 in 418 Appendix B. For the non-toxic (toxic) trap words, we expected MTurk participants to select a score 419 of 1 or 2 (4 or 5) on the Likert scale. Participants were considered unreliable if they did not meet 420 those expectations, and their assessments were discarded from our results. We ended up with 246 421 reliable participants, evenly split between males and females. The majority were educated (74% 422 finished college), mostly located in the United States, falling within the median age group of 26-39. 423 In terms of racial demographics, most were White (52%), followed by Asian (27%), African (7%), 424 and Hispanic (5%).7 425

We collected five annotations per word on average. A word was labeled as a protected attribute if the sum of the votes across the nine categories exceeded the *None of the above* (majority voting).

Machine-in-the-loop setup. We also annotated the same set of words by prompting GPT-3.5 Turbo, as introduced in §3-B2. The temperature parameter was set to 0.3 to limit creativity in
 generating the responses. Other temperature values in the range [0.3, 0.7] have been experimented
 with, although no major differences were observed. For each candidate word, we prompted GPT 3.5-Turbo, asking for a possible protected category, a reliability score, and an explanation for the
 classification. If a word is classified with any protected category, it is labeled as a protected attribute.

4.3.3 Results. The two expert annotators (A1, A2) identified 72/400 (18%) and 66/400 (17%) protected
 attributes, respectively. The human-in-the-loop (MTurk) approach 108/400 (27%) ones. Instead,
 the machine-in-the-loop (ChatGPT) approach labeled 93/400 (23%) words as protected attributes.
 These findings indicate that the original classifier heavily relies on protected attributes for toxicity
 predictions. Interestingly, the ChatGPT *Identifier* is also able to annotate proxy words for the

⁴⁴⁰ ⁷Crowdworkers have been paid for their valuable contributions and time devoted to this research.

442 protected categories. For example, the word '*headscarf*' is annotated as related to *religion and belief* 443 (see Figure 10 in Appendix A). If we use the pre-defined dictionary [6, 20] instead of the *Identifier* 444 component, only 9 out of 400 words (2%) would have been labeled as protected attributes. This 445 suggests that pre-defined dictionaries may consist of a limited subset of protected attributes and 446 not encompass the entire range of relevant attributes.

Figure 5 shows the two-by-two Cohen's kappa inter-annotator agreement between the annotation 447 performed by the two experts (A1, A2), ChatGPT (GPT), MTurk (MT), and the pre-defined dictionary 448 (D). A higher score indicates a greater level of agreement. The score between the two expert 449 annotators is 0.81, corresponding to an almost perfect agreement according to Landis and Koch's 450 scale [41]. The ChatGPT annotations demonstrate substantial (0.67) and moderate (0.56) agreement 451 with the expert annotators. In contrast, the MTurk annotations show a moderate agreement of 452 0.48 and 0.44 with the expert annotators, respectively. The pre-defined dictionary exhibits low 453 agreement with all other annotations, as it only covers a small subset of the important words. 454

This evaluation demonstrates that the machine-in-the-loop approach outperforms the humanin-the-loop one in identifying protected attributes, while also enabling the full automation of the framework. For the next experiments, we thus adopt the LLM-based approach for the *Identifier*.

4.4 Component evaluation: Moderator

460 The *Moderator* aims to create a mitigated training corpus to train a new classifier with reduced 461 reliance on protected attributes and similar predictive performance. To evaluate the effectiveness 462 of each mitigation strategy, we trained and evaluated a distinct mitigated model for each strategy.

Evaluation metrics. For each mitigation strategy, we examine two key aspects of the mit-4.4.1 464 igated classifiers: fairness and predictive performance. Our fairness is defined as fairness through 465 unawareness, whereby "an algorithm is fair as long as any protected attributes are not explicitly 466 used in the decision-making process" [45]. This is quantified by measuring the number of pro-467 tected attributes each mitigated model relies on in making predictions based on the Explainer and 468 Identifier components. A lower number indicates a reduced dependence on protected attributes, 469 which signifies progress towards a more fair and unbiased classifier. To evaluate the predictive 470 performance, we measure the F1 score specifically for the toxicity label, providing insight into the 471 model's accuracy in identifying toxic texts. Additionally, we evaluate the Area Under the Curve 472 (AUC) score for all toxicity-related labels. This metric provides an overall measure of the model's 473 performance in identifying various aspects of toxicity. By considering both fairness and predictive 474 *performance*, we can ascertain the effectiveness of the mitigated models in achieving a balance 475 between reducing reliance on protected attributes and maintaining similar predictive capabilities. 476

477 4.4.2 Moderator setup. For the mitigation strategies outlined in §3-C, we used the following setup: 478 for the removal-based strategies (MS1, MS2), we removed the sentences or the words if, after the 479 tokenization, the protected attributes are in the list of tokens. In the case of the mitigation strategies 480 based on the k-neighbours (MS3, MS4), we set the value of k to 5, meaning that for each protected 481 attribute, the five closest words were identified. To identify these nearest neighbors, we computed 482 the cosine similarity between each word in the vocabulary and the protected attribute using the 483 300-dimensional GloVe [55] word embedding, as suggested in [6]. For the hypernyms-based strategy 484 (MS5), we utilized the WordNet lexical database [46] provided in NLTK [6]. Specifically, we replaced 485 each protected attribute with its first-level hypernym extracted from its synset of synonyms. 486

4.4.3 Training the mitigated models. We applied each mitigation strategy to the original Wikipedia
comments training dataset. Each mitigation strategy produced a modified version of the training
dataset (containing 159,571 examples), whose differences are shown in the third column of Table 1.

490

458

459

A Framework for Mitigating the Use of Protected Attributes

Model	1.1	A	Predictive Performance ↑			Fairness ↓

Table 1. Results in mitigating toxicity prediction on in-distribution data (test set). The original model is highlighted in grey (M_o). For each mitigated model are reported: (1) the model identifier, (2) the mitigation strategy applied, (3) the difference in training examples after the mitigation strategy, (4) the F1 macro and weighted scores for the toxicity class on the original test set, (5) the AUC score for all toxicity-related labels on the original test set, and (6) the percentage and ratio of relied-upon protected attributes, with the number of those present in the original model in brackets. The best performing for each metric is in bold.

The sentence-removal mitigation strategy (MS1) resulted in a decrease of 6k examples. Instead, the strategy that added k new sentences for each protected attribute (MS4) increased the training dataset by 108k new sentences. The other mitigation techniques did not change the number of training examples. All mitigated models $(M_1^*-M_5^*)$ were trained by fine-tuning the original pre-trained weights of BERT⁸ for 3 epochs, with a batch size of 16, and Adam [36] as optimizer.

To evaluate the mitigated models, we first classified all texts in the test set with each *mitigated* model. Then, we applied the *Explainer* to extract the most important predictive words used by each *mitigated* model for the toxicity predictions in those texts. Finally, we exploited the *Identifier* to determine if the new important words of the mitigated models were protected attributes.

515 516

517 Fairness. The last two columns in Table 1 show the percentage and number of the most toxic words 518 labeled as protected attributes for all the mitigated models $(M_1^* - M_5^*)$. The number of those already 519 present among the protected attributes of the original model (M_0) is indicated in square brackets. 520 All the mitigation strategies reduced the number of protected attributes the model relied upon. 521 However, the mitigated models trained with removal-based strategies (MS1, MS2) achieved much 522 better results. Only 9% and 10% of their most toxic words were labeled as protected attributes (37 and 523 40 words out of 400), representing a decrease of 61% from the original model (93 words out of 400). 524 One possible reason for the lower performance of replacement-based mitigation strategies (MS3-525 MS5) is that they can introduce new protected attributes when replacing words. For a qualitative 526 evaluation of fairness improvement, please refer to Figures 11 and 12 in Appendix C. 527

Predictive performance. In Table 1, columns 4 and 5 report the macro and weighted F1 scores 528 on the toxicity label for the original and mitigated models. Column 6 also presents the mean 529 AUC scores across all the toxicity-related labels. The results show that all the mitigated models 530 present similar F1 scores compared to the original model, except for the one trained with MS4, 531 which exhibits a greater decrease. Interestingly, the mitigated models trained on the removal-based 532 mitigation strategies (MS1, MS2) achieve better F1 scores than the original model. The word-removal 533 (MS2) increases the macro and weighted F1 scores by 1.3% and 1.2%. Indeed, we observed that the 534 removal-based mitigation strategies reduced the number of false positives in the toxicity predictions 535 (i.e., non-toxic texts wrongly predicted as toxic). All the mitigated models exhibit slightly lower 536

⁸https://huggingface.co/bert-base-uncased

AUC scores compared to the original model. However, the decrease is minor and acceptable (around
0.5% and 0.3%) in light of the reduced reliance on protected attributes.

Summary. We conclude that our framework effectively reduces the model's reliance on protected attributes without compromising its predictive performance. Indeed, all mitigated models are fairer in that they significantly reduce the use of protected attributes and exhibit similar predictive performance to the original model. Interestingly, the removal-based strategies (MS1, MS2) even increased the models' predictive performance after the mitigation.

548 5 FRAMEWORK EVALUATION: GENERALIZABILITY

We finally evaluate the generalizability of our framework first to toxicity prediction on out-of distribution data (§5.2), and second on different tasks, i.e., sentiment analysis (§5.3) and occupation
 classification (§5.4).

553 5.1 Framework and evaluation settings

554 For this evaluation, we instantiated the Explainer with Integrated Gradients, the Identifier with 555 ChatGPT, and the Moderator with the removal-based mitigation strategies. As shown in §4, this 556 turned out to be the optimal framework configuration. We perform a similar evaluation of the 557 mitigated models by measuring their fairness and predictive performance. Fairness is evaluated by 558 quantifying the number of protected attributes each mitigated model relies on (fairness through 559 unawareness). Predictive performance is evaluated using quantitative metrics on the test set. For 560 the toxicity classifier, we measure the F1 score for the toxicity label, which allows us to gauge the 561 model's accuracy in detecting instances of toxicity, and the Area Under the Curve (AUC) score for 562 all toxicity-related labels, providing an overall assessment of the model's performance in identifying 563 different aspects of toxicity. For the sentiment and the occupation classifiers, we solely measure 564 the F1 score, as it provides a comprehensive assessment of the model's accuracy in these tasks. 565

566 5.2 Mitigating toxicity prediction on out-of-distribution data

This experiment aims to assess the applicability of our framework in mitigating the toxicity model when applied to out-of-distribution data, specifically company reviews. This is crucial as classifiers are normally applied to datasets from other domains with different word distributions from training.

5.2.1 Company reviews data. We collected data from a popular online platform where current and 571 former employees write reviews about companies. Reviewers comment on various aspects such as 572 personal experience with the company or managers, salary information, workplace culture, and 573 typical job interviews. The platform fosters a constructive approach among its users by manually 574 and automatically moderating the content of reviews. However, reviews are published anonymously. 575 On the one hand, this promotes user privacy. On the other hand, it can also cause some users to 576 write public insults and offenses toward companies or people. Specifically, we collected a dataset of 577 439,163 reviews from U.S.-based companies across all 51 U.S. states written from 2008 to 2020.⁹ Each 578 review contains a pros part (positive comments in the review) and a cons part (negative comments). 579 We applied the same toxicity classifier introduced in §4.1 to identify toxic company reviews. 580

5.2.2 Toxicity in company reviews. The initial expectation was not to have many toxic reviews in
 the dataset due to the highly curated nature of the platform. However, if we consider a post to be
 toxic when at least one of the cons or pros fields contains inappropriate content, we found 1.6% of
 reviews (7,224) to be toxic. The number of reviews classified as toxic by using the pros and cons
 texts as input is 853 for pros (0.2%) and 6,495 for cons (1.5%) over 439,163. As expected, we found

⁵⁸⁷ ⁹To preserve the privacy of individuals, Personally Identifiable Information (PII) was removed.

⁵⁸⁸

A Framework for Mitigating the Use of Protected Attributes

CSCW'24, November 9-13, 2024, San José, Costa Rica

Model		∆ Train	Predictive Performance ↑			Fairness ↓	
ID	Mitigation Strategy	Examples	F1 Macro	F1 Weight	AUC	% P A	Ratio PA
Mo	-	-	0.815	0.926	0.986	19%	76/400
$egin{array}{c} M_1^* \ M_2^* \end{array}$	MS1 - Sentence removal MS2 - Word removal	-6k -	0.824 0.825	0.938 0.935	0.979 0.983	4% 5%	16/400 [8] 19/400 [11]

Table 2. **Results in mitigating toxicity prediction on out-of-distribution data (company reviews).** The original model is highlighted in grey (M_o). For each mitigated model are reported: (1) the model identifier, (2) the mitigation strategy applied, (3) the difference in training examples after the mitigation strategy, (4) the F1 macro and weighted scores for the toxicity class on the original test set, (5) the *AUC* for all toxicity-related labels on the original test set, and (6) the percentage and ratio of relied-upon protected attributes, with the number of those present in the original model in brackets. The best performing for each metric is in bold.

that most of the toxic texts are present in *cons*. Interestingly, some people tend to be so angry and frustrated by the work experience that they let off steam even in the *pros* field.

603 Identify protected attributes in toxicity predictions on company reviews. All pros and cons 5.2.3 604 reviews predicted as toxic were analyzed by the Explainer component to extract the most important 605 words used by the model in predicting toxic reviews. Then, we selected the 400 most toxic words 606 extracted, and we annotated those words with GPT-3.5-Turbo. Among the 400 most important 607 words used by the model in predicting toxic reviews, 76 are protected attributes (19%), as shown 608 in the last two columns of the first row in Table 2 (original model M_o). We can conclude that the 609 original classifier exhibits a significant reliance on protected attributes for toxicity predictions, 610 even when applied to different out-of-distribution data. 611

Training the mitigated models. We applied the removal-based mitigation strategies (MS1, MS2) 5.2.4 612 to the original Wikipedia comments training dataset based on the protected attributes identified 613 in the toxic company reviews. Table 2 shows the differences in the number of training examples 614 after each strategy in the third column. The original training dataset contained 159,571 examples. 615 MS1 resulted in a decrease of 6k examples, while MS2 did not change it. All mitigated models 616 were fine-tuned for 3 epochs, with a batch size of 16, and Adam as optimizer. To evaluate the 617 mitigated models, all pros and cons reviews were classified by each mitigated model. Then, we 618 applied the Explainer component to extract the most important 400 predictive words used by each 619 mitigated model for the toxicity predictions on company reviews. Finally, we exploited the Identifier 620 to determine if the new important words of the mitigated models were protected attributes. 621

5.2.5 Results.

Fairness. The last two columns in Table 2 show the percentage and number of the most toxic words labeled as protected attributes. The number of those already present among the protected attributes used by the original model (M_o) is also indicated in square brackets. The results confirm that removal-based mitigation strategies reduce the number of protected attributes the model relied upon. MS1 and MS2 reduce the percentage of protected attributes from 19% to 4% and 5% (16 and 19 out of 400 words), respectively. This corresponds to a decrease of 79% and 75%. They also reduce the protected attributes the original classifier relies on from 76 to 8 and 11, respectively.

Predictive performance. Columns 4 and 5 in Table 2 show the macro and weighted F1 scores achieved by the original and mitigated models on the test set. The mitigated models exhibit higher predictive performance in terms of F1 scores than the original model. The increment is around 1% for both scores and mitigated models. Finally, column 6 shows the *AUC* for all the toxicity-related labels. The mitigated model produced by MS1 achieves 0.979 on the *AUC* score, with a decrease of 0.007 from the original model. Instead, with MS2, the decrease in performance is only 0.003.

637

622

623

638	Model		ΔTr	ain	Predictive 🛧		Fair	ness↓	
639	ID	Mitigation Strategy	Examples Negative Positive		Performance F1	Nega % PA	itive Class Ratio PA	Posi % PA	tive Class Ratio PA
640	Mo	-	-	-	0.96	8%	16/200	6%	11/400
641 642	$egin{array}{c} M_1^* \ M_2^* \end{array}$	MS1 - Sentence removal MS2 - Word removal	-5k -	-8k -	0.96 0.96	4% 8%	8/200 [2] 16/200 [2]	3% 6%	5/200 [1] 11/200 [2]

Table 3. **Results in mitigating sentiment analysis.** The original model is highlighted in grey (M_0). For each mitigated model are reported: (1) the model identifier, (2) the mitigation strategy applied, (3) the difference in training examples after the mitigation strategy for the *negative* and *positive* classes, (4) the F1 macro score on the original test set, and (5) the percentage and ratio of relied-upon protected attributes, with the number of those present in the original model in brackets, for both classes. The best performing for each metric is in bold.

Summary. The experimental results obtained from the out-of-distribution data demonstrate the capability of our framework to effectively mitigate a model's reliance on protected attributes when applied to non-training data, where ground truth labels are unavailable. It showcases its adaptability and robustness in real-world scenarios where labeled data may not be readily accessible.

⁶⁵⁴ 5.3 Mitigating sentiment analysis

This evaluation aims to assess the versatility and effectiveness of our framework across different
 classification tasks. For this experiment, we chose sentiment classification to test our framework in
 mitigating the use of protected attributes for tasks where their reliance might be lower.

5.3.1 Training the original sentiment classifier. We selected a dataset of 163K tweets and 37K Reddit
 comments in English, expressing people's opinions towards the general elections held in India in
 2019.¹⁰ The task consists of a multi-class sentiment classification problem with 3 classes: *negative*,
 neutral, and *positive*. We split the dataset with 80% for training (160k) and 20% for testing (40k). We
 fine-tuned the BERT model for 3 epochs, achieving a 0.96 F1 score on the test set.

664 Identifying protected attributes in sentiment predictions. We used the fine-tuned model to 5.3.2 665 predict the sentiment label over the entire test set. Then, we analyzed, separately, all the *negative* 666 and positive texts with the Explainer component instantiated with Integrated Gradients. The neutral 667 texts do not contain specific patterns that the model should learn and are not of interest for 668 mitigation. Then, we annotated with GPT-3.5-Turbo the 5% of the most important words for the 669 negative and 5% for the positive texts separately, resulting in the top 200 negative and 200 positive 670 words. We found that 16 (8%) of 200 negative words and 11 (6%) of 200 positive words were labeled 671 as protected attributes by the Identifier, suggesting a moderate reliance on protected attributes. 672

5.3.3 Training the mitigated models. We applied the two removal-based mitigation strategies (MS1,
MS2). In this case, the mitigation is performed separately per class label (e.g., the protected attributes
in the most negative words are mitigated only on the negative training examples). MS1 decreases
the training set by 5k *negative* and 8k *positive* training examples, as shown in the third and fourth
columns in Table 3. Also in this case, the models were fine-tuned for 3 epochs.

We used the *mitigated* models to predict the sentiment label over the test set. Then, we extracted the most important 200 words from the *negative* and *positive* texts separately with the *Explainer*, and we annotated those words with the *Identifier*.

682 5.3.4 Results.

Fairness. The last four columns in Table 3 show the percentage and the number of protected

⁶⁸⁴ ¹⁰https://www.kaggle.com/datasets/cosmos98/twitter-and-reddit-sentimental-analysisdataset

686

678

649

650

651

652

attributes of the original (M_o) and mitigated $(M_1^*$ and $M_2^*)$ sentiment classifiers for the *negative* and 687 positive classes, separately. MS1 produces a mitigated model that relies on half of the protected 688 attributes of the original classifier (4% for the negative and 3% for the positive classes). Interestingly, 689 the number of protected attributes the original classifier relied on is almost completely mitigated, 690 except for 2 for the negative and 1 for the positive classes. MS2 has a similar behavior in this. 691 However, many new protected attributes emerge as new important words. In the end, the total 692 number of protected attributes remains the same, even though the protected attributes of the 693 original model have almost all been mitigated. Therefore, MS1 is the most effective in this case. 694

Predictive performance. The fifth column in Table 3 shows the F1 score obtained by the original
 sentiment classifier and the mitigated models on the test set. The mitigated models achieve the
 same F1 score, thus showing the same predictive capabilities.

Summary. These results show that our framework can be effective not only on the toxicity model, which heavily relies on protected attributes, but also on the sentiment model, which is moderately impacted by protected attributes, confirming its general effectiveness.

5.4 Mitigating occupation classification

This evaluation serves three primary objectives: (1) to further assess the adaptability and effectiveness of our framework across various classification tasks, (2) to mitigate the use of protected attributes in scenarios where the final prediction has tangible consequences for individuals, and (3) to compare our framework with two mitigation techniques that act on the model rather than data.

707 To achieve these goals, we selected the task of predicting occupations from online biographies, 708 using a dataset of biographies annotated by gender and occupation from previous works [17, 54, 58]. 709 We used the field 'cleaned_input_text' as input text, where sentences that directly reveal the 710 occupation were removed (e.g., "he is a journalist"), and we removed first names. We compare our 711 framework with two model-based mitigation techniques: Iterative Null-space Projection (INLP) [58] 712 and Entropy-based Attention Regulation (EAR) [4]. INLP requires an additional annotation for the 713 mitigated category, which is only present for gender in this dataset. Therefore, we conduct two 714 distinct analyses: (1) focusing solely on gender-related, and (2) examining all protected categories 715 together. For the gender-related protected attributes, we compare both baselines with our word-716 removal (MS2). Instead, we use only EAR as a baseline to mitigate all the protected categories. We 717 chose MS2 because it has shown similar mitigation effectiveness while maintaining competitive 718 performance, but it has higher flexibility across datasets than sentence-removal (MS1) (see §6.3). 719

720 5.4.1 Training the original occupation classifiers. The dataset contains 393,423 biographies for 28 occupations split into 255,710, 39,369, and 98,344 train, dev, and test examples. We fine-tuned 721 a BERT-base and uncased model for each occupation in one-vs-all settings (i.e., a binary model 722 that predicts the occupation or not for each label). Due to the high imbalance of the dataset, 723 we performed the experiments for the five most frequent classes (i.e., nurse, attorney, journalist, 724 physician, and professor). The models were fine-tuned for 3 epochs.¹¹ The second column in Table 4 725 shows the macro F1 score on the test set for each original model trained for four occupations.¹² 726 Those models are highly effective in classifying occupations, achieving a macro F1 score higher 727 than 0.89. Still, such high performance could be achieved by heavily using protected attributes. 728

5.4.2 Identifying protected attributes in occupation classification. We used each original model to
 predict each occupation label over the entire test set and analyzed those texts using the *Explainer* to extract the most important words in predicting each occupation. Then, for each occupation, we

735

702

703

704

705

⁷³³ ¹¹We utilized inversely proportional class weights in the loss function due to the highly imbalanced training dataset.

¹²Results for the *professor* occupation are not reported since the model do not rely on gender-related protected attributes.

736			Original Mo		Mitigation		0	ed Models

748 Table 4. **Results in mitigating occupation classification.** For the *original* models (highlighted in grey), trained in one-vs-all settings, are reported the macro F1 and the reliance on protected attributes (PA) for gender 749 only and all categories. For each occupation, we applied our framework with the word-removal strategy (MS2) 750 on gender-related only and all categories of protected attributes training two different *mitigated* models. 751 For EAR [4], a single model was trained but evaluated on different protected categories. INLP [58] is only 752 applicable to gender-related protected attributes in this dataset. For each mitigated model are reported: (1) 753 the mitigation technique, (2) the macro F1 score for the occupation classification on the test set (predictive 754 performance), and (3) the ratio and percentage of relied-upon protected attributes, with the number of those 755 present in the original model in brackets (fairness). The best performing for each metric is in bold.

annotated with GPT-3.5-Turbo the top 400 words to identify protected attributes. We measured 759 the models' reliance on protected attributes related to (1) gender only, and (2) all categories (third 760 and fourth columns in Table 4). All the models moderately rely on protected attributes. The nurse 761 occupation is the most influenced, also by gender-related words, such as pronouns (e.g., 'she', 'her'). 762

763 5.4.3 Training the mitigated models. With our framework, we applied the word removal mitigation 764 strategy (MS2) for each occupation on (1) gender-related only, and (2) all the protected categories 765 simultaneously. Therefore, we trained two different mitigated models for each occupation. We 766 trained one mitigated model for each occupation with the INLP methodology [58]. INLP can mitigate 767 the gender-related protected attributes but is not applicable to all the other categories, since the 768 dataset contains the additional annotation only for gender. Specifically, we used the original pre-769 trained BERT weights as the encoder. Then, we multiplied the embedding representation of the 770 [CLS] token from the last hidden layer for each input text by the projection matrix produced by the 771 INLP technique (to ensure that the embedding representation does not encode information about 772 gender). Finally, we added a classification layer on top. We fine-tuned only the classification layer 773 while freezing the BERT encoder and the projection matrix, as suggested in [58]. For EAR [4], we 774 used the same BERT architecture, and we added the loss function regularization term, with 0.001 as 775 regularization strength. EAR does not allow the selection of which protected categories to mitigate, 776 but it identifies by itself which words have a high attention entropy. Thus, we trained a single 777 mitigated model, and we evaluated its reliance on gender and all protected categories separately.

778 We used the mitigated models to predict the occupation labels over the entire test set, we extracted 779 the most important 400 words for each occupation separately with the Explainer, and we annotated 780 those words with the *Identifier* to evaluate if they exhibit a reduced reliance on protected attributes. 781

5.4.4 Results. 782

Fairness. Columns 7 and 9 in Table 4 show the number and percentage of protected attributes 783

784

on which the mitigated models rely for gender only and all categories separately. The number of 785 these words already present among the ones used by the original model is also indicated in square 786 787 brackets. The objective of each *mitigated* model is to reduce the reliance on protected attributes (columns 7 and 9) compared to the respective original model for each occupation (columns 3 and 4). 788

Concerning gender (column 7), our framework is the most or as effective as other techniques in 789 mitigating the use of such protected attributes. For the *nurse* occupation, which represents the model 790 showing a greater dependence on gender-related protected attributes, our framework reduced the 791 792 number of the most significant gender-related words from 11 to 2. One of these two gender-related words was already significant in the original model. INLP obtained a similar mitigation effect, while 793 EAR is less effective, with 4 gender-related protected attributes still important for the mitigated 794 model. For the *attorney* and *physician* occupations, the original model exhibited a lower reliance on 795 gender-related protected attributes, and our framework was able to fully mitigate the use of those 796 words. On average, our framework reduces reliance on gender-related protected attributes by 79%. 797

The results are similar when considering all protected categories (column 9). Our framework is 798 always more effective than EAR in mitigating the use of protected attributes, except for the nurse 799 occupation, where both techniques achieve the same mitigation effect. On average, our framework 800 successfully reduces reliance on all categories of protected attributes by 43%. 801

802 Predictive performance. Columns 6 and 8 in Table 4 show the macro F1 score achieved on the test 803 set by each mitigated model. The objective of each mitigated model is to achieve similar predictive 804 performance (columns 6 and 8) compared to the respective original ones (column 2). The mitigated 805 models produced by our framework and the EAR technique achieve similar or sometimes even 806 better performance than the original model (e.g., for the *journalist* and *physician* occupations). 807 Therefore, they are able to mitigate the use of protected attributes without sacrificing predictive 808 performance. Instead, the INLP technique is able to produce models with mitigated bias at the cost 809 of significantly reducing their performance. Indeed, all the mitigated models produced by INLP 810 experienced an average loss in predictive performance of 10%. This tendency to achieve fairness by 811 making every advantaged group worse off or by bringing better performing groups down to the 812 level of the worst off is a common undesirable behavior of bias mitigation techniques [48].

813 Summary. These results confirm the effectiveness of our framework in a different task where 814 the protected attributes are strictly related to individuals. They show that our framework is more 815 effective in achieving such an objective than previous bias techniques, while also providing the 816 flexibility to select which protected category to mitigate. This flexibility enables the mitigation of 817 only a subset of protected categories when some are required for the task at hand. 818

6 DISCUSSION

Our results show how the proposed framework could be exploited to train a new classifier that mitigates the use of protected attributes while maintaining competitive performance. We evaluated 822 its sensitivity to each component and its effectiveness in mitigating a toxicity classifier. We also 823 proved its generalizability on models applied to out-of-distribution data (i.e., toxicity on company 824 reviews) and two other tasks (i.e., sentiment analysis and occupation classification). Removal-based 825 strategies (MS1, MS2) have been shown to be the most effective mitigation techniques. We also 826 show that the LLM-based Identifier outperforms the crowdsourcing one, allowing the automation of the framework, and a dynamic updating of the dictionary of protected attributes. 828

Framework integration, versatility and complexity 6.1

Integration. Our framework can be integrated into existing NLP pipelines for two main purposes. (1) The Explainer and Identifier can be used to measure and evaluate existing NLP classifiers'

819

820

821

827

829

830

reliance on protected attributes. As a result, models can be quantitatively compared not only through 834 predictive performance and traditional fairness metrics (e.g., conditional demographic disparity [74]) 835 836 but also through the use of protected attributes in predictions. (2) The entire framework can be used to train a new model with reduced reliance on protected attributes and competitive performance. 837 Our framework can also be integrated to complement other bias mitigation techniques acting in 838 both the model and data spaces that require pre-defined dictionaries or lists of protected attributes 839 or identity terms. The *Explainer* can improve existing techniques to pinpoint the specific words 840 841 the model mostly uses for the classification rather than looking at all possible words in the corpus. The Identifier can annotate protected attributes covering a broader range of categories, as many 842 protected attributes, such as disability or religious belief, were rarely covered by prior studies. 843

- 844 Versatility. Our framework is designed to achieve fairness through unawareness by mitigating the 845 model's reliance on protected attributes in predictions. It addresses multiple categories simulta-846 neously. Therefore, it can potentially address intersectional bias, i.e., that encompasses multiple 847 sensitive attributes together [24]. Moreover, it provides users the flexibility to choose which cate-848 gories to mitigate, thanks to the fine-grained annotation performed by the Identifier. Such flexibility 849 is particularly useful when some categories are indispensable or aimed at the prediction task. 850 Through this, our framework can address domain-specific bias related to the classification task (e.g., 851 gender-related protected attributes in occupation classification). Consequently, in scenarios where 852 the inclusion of certain protected attributes is necessary for accuracy, our framework can still be 853 utilized to effectively mitigate all other protected attributes that are not essential for the task.
- 854 **Complexity.** The execution time to produce the mitigated training dataset depends on many factors. 855 Given a fixed model complexity, the execution times increase linearly with: (1) the unlabeled corpus 856 size, (2) the number of most important words annotated, and (3) the training dataset size. Increasing 857 the model's complexity results in a slight increase in the execution time of all components. Our 858 framework yields a mitigated training corpus, necessitating extra training to produce the mitigated 859 model. The (re-)training time varies based on model complexity and original data size. Techniques 860 such as MS2, MS3, and MS5 maintain dataset dimensionality, resulting in comparable training times 861 for both original and mitigated models. Conversely, MS1 reduces or MS4 increases dataset size, 862 affecting training time accordingly. An example of execution time is reported in Appendix D. 863

6.2 Implications

865 Our research significantly contributes to the CSCW community by exploring human-AI collab-866 oration, especially in decision-making contexts. For example, our tool could assist humans in 867 comprehending the hiring decisions made by NLP classifiers and address biases in the hiring 868 process [53]. Our work extends into content moderation, empowering the development of robust 869 systems capable of effectively identifying and mitigating toxic content while ensuring fairness. This 870 aids humans in understanding crucial moderation aspects, encompassing significant words and 871 considerations around protected attributes, to foster collaboration with machines to collectively 872 arrive at fair decisions in content moderation. Our work has three main implications: 873

Fully-automated framework for compliant NLP classifiers. We release an open-source frame work.¹³ By leveraging LLM annotations, it operates in a fully automated manner. The mitigated
 models exhibit enhanced fairness by significantly reducing their reliance on protected attributes
 while maintaining comparable or even better predictive performance. Other researchers can utilize
 our framework to address the compliance standards set by regulators, whether by mitigating
 already trained models or incorporating them into future models. This contribution empowers the

864

⁸⁸⁰ 881

¹³The code repository of our framework is available at https://github.com/grecosalvatore/nlpguard

community to uphold ethical standards and ensure fairness in NLP applications. For example, the
 mitigated toxicity classifiers can be used for online moderation in compliance with AI regulations.

885 Protected attributes annotation. We advanced the literature in the protected attributes iden-886 tification in NLP, traditionally done with static and manually pre-defined dictionaries covering 887 only a subset of categories. However, they are difficult to keep up-to-date, especially with the 888 emergence of ever-evolving language trends and slang. In our framework, we demonstrated a novel 889 approach to dynamically identify protected attributes through straightforward prompts to an LLM. 890 This enables the creation of a comprehensive and up-to-date dictionary covering all the protected 891 categories simultaneously, which can be updated periodically, ensuring its relevance in real-time 892 linguistic landscapes.

In our research, we annotated 15,000 words, 540 labeled as protected attributes. We release
 our dictionary in the GitHub repo. It is more comprehensive, covers a broader range of protected
 categories than existing dictionaries, and can be continuously updated by exploiting our identifier.
 Researchers can use and enhance this resource to advance bias mitigation in NLP.

Humans vs. LLM annotations. Building upon a recent finding [23], our study demonstrates that LLM annotation can outperform human-in-the-loop crowdsourcing annotations. Within our framework, we establish that LLM-based annotation of protected attributes proved to be more cost-effective and scalable, and aligns closely with expert annotations. This allows us to design a fully automated framework without human intervention. This finding opens new avenues for exploring the potential of LLMs as an effective tool for obtaining high-quality annotations.

6.3 Limitations and Future Directions 906

Our current approach has six main potential limitations or areas of concern.

Context unawareness. Our Identifier and Moderator label and mitigate words related to pro-908 tected attributes without considering context, simplifying annotation but risking inaccuracies. For 909 instance, 'black' may be a protected attribute in one context ("If you are a guy (black) or lesbian 910 you get hired fast") but not in another ("I bought a new black desk"). Addressing context could 911 enhance mitigation effectiveness yet poses challenges in the identification and mitigation phases. 912 Human-in-the-loop context annotation is costly, requiring thousands of context-aware annota-913 tions, potentially increasing noise. Machine-in-the-loop is more scalable but complicates prompt 914 engineering, potentially leading to misunderstandings and noisy responses [43]. We conducted 915 a preliminary experiment assessing context-aware annotation's impact on identifying protected 916 attributes with LLM. Repeating annotations with up to 10 context sentences, we found a 75% overlap 917 between word-level and context-level annotations, with some contradictions, especially for long 918 sentences. However, future research should explore this further across datasets. 919

Potential bias introduced by the Identifier. The annotation of protected attributes is a subjective 920 task. Therefore, the Identifier can potentially introduce further sources of bias. In human-in-the-921 loop settings, crowdworkers should come from various backgrounds to have a broader contextual 922 understanding during the annotation process. The distribution of the demographic backgrounds of 923 crowdworkers can have an impact on the annotated protected attributes. It is important to ensure 924 an equitable distribution of crowdworkers across all protected categories. However, this can often 925 be challenging in practice. Instead, in the machine-in-the-loop settings, the Identifier can introduce 926 potential bias inherent in the LLM system adopted. The LLM can associate certain words with 927 protected attributes based on stereotypes prevalent in the training data. However, addressing bias 928 inherent in LLM is an active area of research expected to resolve numerous current limitations, 929 significantly enhancing the effectiveness of our framework. Finally, introducing specific definitions 930

931

898

899

900

901

902

903 904

of protected attributes, such as the nine categories defined by the UK Equality Act 2010, might also inadvertently introduce biases or overlook certain nuances in both human annotators and LLMs.

934 Reliance on XAI techniques. Our framework relies on XAI techniques to identify the most 935 important words for the model. Nevertheless, it is important to acknowledge that XAI methods 936 have inherent limitations [47, 65], including challenges like effective aggregation and normalization 937 methods, and the contextual variability of words across different explanations. These limitations 938 may hinder the accurate extraction of the most important words used by the model, affecting the 939 *Identifier* in the identification of protected attributes that the model relies on to make predictions. 940 This issue can extend to the *Moderator*, impacting the mitigated protected attributes. In the future, 941 improvements in the XAI field could make our framework even more effective. This is because 942 our framework is flexible and can use any feature importance explainability method that can be 943 applied to a pre-trained classifier (e.g., Integrated Gradients or SHAP), as explained in §3-A. 944

Defined protected categories. Our framework annotates protected attributes based on the nine 945 categories outlined in the Equality Act 2010. These categories represent a significant step toward 946 addressing discrimination and promoting equality. However, they might not cover all aspects of 947 human diversity or potential discrimination. Since they were formalized in 2010, some characteristics 948 remain unaddressed by the Act. More than a decade later, initiatives are underway to broaden 949 these categories for aspects like socio-economic status, health status, genetic heritage, and physical 950 appearance [50]. Future extensions will further enhance the comprehensiveness of our framework 951 in encompassing a broader range of protected categories. Notably, for the LLM-based annotation, 952 incorporating new categories is a straightforward process that involves modifying the prompt. 953

Mitigation with small training datasets or common protected attributes. In scenarios with 954 small or imbalanced training data, or when protected attributes are common in most input texts 955 (e.g., 'he' and 'she' in biographies), sentence removal (MS1) may be less effective due to potential 956 consequences of removing sentences containing protected attributes from already limited datasets. 957 Frequent presence of common protected attributes in inputs may exclude most sentences, reducing 958 available training data significantly. This reduction can cause a significant and unacceptable 959 decrease in model accuracy. Hence, alternative strategies, like word-removal (MS2), should be 960 considered. MS2 has similar effectiveness in mitigating protected attributes while maintaining 961 predictive performance, offering flexibility across datasets without suffering from these issues. 962

Fairness-privacy tradeoff. Our approach neither protects the privacy of individuals nor considers 963 words or sentences to be private. Instead, it focuses on constraining the classification so that does 964 not rely on protected attributes. In the way that loans cannot be given by an automatic system that 965 relies on racial backgrounds, natural language classification should not rely on protected attributes. 966 The tradeoff between fairness and privacy becomes more pronounced when considering human-967 and machine-in-the-loop identifiers. The protected attributes annotation requires exposing textual 968 sensitive information to individuals who are not necessarily trusted or to LLMs. This creates a risk 969 of privacy violations and potential harm to the individuals whose sensitive information is being 970 used [1]. The proposed methodology requires careful consideration of the privacy-fairness tradeoff. 971

In future work, we plan to develop a context-aware framework that would allow us to identify and mitigate protected attributes based on their context by extracting the words and context information from the dataset, identifying protected attributes within each context, and applying mitigation strategies only to those sentences that contain protected attributes in similar contexts.

1226 APPENDIX

The Appendix sections are organized as follows. Appendix A shows the LLM prompts used by
 the *Identifier* to annotate words related to protected attributes. Appendix B shows the list of trap
 words used in the MTurk study. Appendix C qualitatively shows the fairness improvement of one
 mitigated model. Appendix D discusses the framework's running time.

1232 A. LLM prompts

1263

1264 1265

The LLM prompts used by the *Identifier* component to annotate words related to protected attributes (as described in §3-B2). A first prompt (Figure 6) provides the protected categories and their definitions. A second prompt (Figure 7) suggests some links that provide more information about the protected categories. Then, for each word, the LLM is asked to: (1) classify the word into one of the protected categories or none of them; (2) provide a reliability score in the range [0, 100]; and (3) provide an explanation. Figure 9 shows the response provided by GPT-3.5-Turbo for the annotation of the word *'homosexual'*, classified with the category *sexual orientation* and a score of 100/100.

The LLM-based *Identifier* is also able to annotate proxy words that, although not directly and strictly related to a protected attribute, can be used by the model to infer the categories. An example is shown in Figure 10, where the word *'headscarf'* is annotated as related to *religion and belief*.

1243 USER: Consider these 9 protected categories defined by the Equality Act law to avoid discrimination of 1244 automatic decision-making algorithms: 1245 "Age": A person belonging to a particular age or range of ages (for example, teenagers). 1246 "Disability": A person has a disability if she or he has a physical or mental impairment which has a 1247 substantial and long-term adverse effect on that person's ability to carry out normal day-to-day activities. 1248 "Gender reassignment": The process of transitioning from one sex to another. 1249 "Marriage and civil partnership": Marriage is a union between a man and a woman or between a same-sex 1250 couple. Same-sex couples can also have their relationships legally recognised as 'civil partnerships'. Civil 1251 partners must not be treated less favourably than married couples. 1252 "Pregnancy and maternity": Pregnancy is the condition of being pregnant or expecting a baby. Maternity 1253 refers to the period after the birth, and is linked to maternity leave in the employment context. In the 1254 non-work context, protection against maternity discrimination is for 26 weeks after giving birth, and this 1255 includes treating a woman unfavourably because she is breastfeeding. 1256 "Race": Refers to the protected characteristic of race. It refers to a group of people defined by their race, 1257 colour, and nationality (including citizenship) ethnic or national origins. 1258 "Religion and belief": Religion refers to any religion, including a lack of religion. Belief refers to any 1259 religious or philosophical belief and includes a lack of belief. Generally, a belief should affect your life 1260 choices or the way you live for it to be included in the definition. 1261 "Sex": A man or a woman. 1262

"Sexual orientation": Whether a person's sexual attraction is towards their own sex, the opposite sex, or both sexes.

Fig. 6. Prompt 1. It provides the definition of the nine protected categories to the LLM.

Fig. 7. Prompt 2. It suggests links which provide more information on the protected categories to the LLM.

USER: Given the previously defined protected categories "Age", "Disability", "Gender reassignment", "Marriage and civil partnership", "Pregnancy and maternity", "Race", "Religion and belief", "Sex", and "Sexual orientation". How would you classify the word "{word}" and which [0,100] reliability score (only one) would you give to your assessment? You must assign one category. If a word does not fit any categories, you must assign the category "None" with the reliability score and the relative explanation. Provide the answer in the format: "Protected Category|Reliability Score from 0 to 100 for the protected category|Explanation of why the word belongs to the protected category". In case a word does not fall into any category, provide the answer in the format: "None|Reliability Score from 0 to 100 for the None category|Explanation of why the word does not fall under any of the defined protected categories. Each answer must have exactly two | symbols in only one line; otherwise, I cannot process your response.

Fig. 8. **Prompt 3**. For each of the most important words, the LLM is asked to (1) classify the word into one of the protected categories or none of them; (2) provide a reliability score in the range [0, 100]; and (3) provide an explanation for the classification. A new request is sent to the LLM for each word by replacing the placeholder {word} in the text.

GPT-3.5-Turbo: Sexual orientation | 100 | Homosexual refers to a person's sexual orientation, specifically indicating attraction to people of the same sex. It falls under the protected category of sexual orientation.

Fig. 9. GPT-3.5-Turbo annotation of the word {HOMOSEXUAL}, categorized as "sexual orientation".

GPT-3.5-Turbo: Religion and belief | 90 | The word 'headscarf' is commonly associated with religious beliefs, particularly in Islam, where it is worn by women as a symbol of modesty and religious observance.

Fig. 10. GPT-3.5-Turbo annotation of the word {HEADSCARF}, categorized as "Religion and belief".

Table 5 shows the list of trap words used in the MTurk for the *Identifier* in the *machine-in-the-loop*setup (§4.3). They were chosen for their ability to be easily classified as toxic or non-toxic, and
were used to detect random responses by MTurk participants. For the non-toxic (toxic) trap words,
we expected MTurk participants to select a score of 1 or 2 (4 or 5) on the Likert scale. Participants
were considered unreliable if they did not meet those expectations, and their assessments were
discarded from our results.

Expected Label	Expected Score	Trap Words
Non-Toxic	1, 2	beautiful, good, trustful, love, great, curiosity, generous, friendly, sweet, happy, helpful, loyal
Toxic	4, 5	asshole, dickhead, motherfucker

Table 5. List of the trap words used in the MTurk study. They were chosen for their ability to be easily classified as toxic or non-toxic to identify random or unreliable responses. By selecting the expected score on the Likert scale for these trap words, the reliability of participants in the study could be determined.

1341 C. Fairness improvement of a mitigated model: a qualitative analysis

1342 Figures 11 and 12 show the fairness improvement of a mitigated classifier for toxicity predictions 1343 in the in-distribution experiment (discussed in §4.4). They show the prediction on the same texts 1344 discussed before (see Figures 1 and 2 in §1) made by one mitigated model (M_2^*) . The first three 1345 sentences (misclassified by the original model) are not predicted as toxic anymore, as the model is 1346 not extensively using the words 'black', 'homosexual', and 'gay' for toxicity predictions anymore. 1347 The fourth sentence is still correctly predicted as toxic. However, the prediction is influenced by 1348 words such as 'hate', 'fucking', and 'shitty' and not by 'black' anymore. These results show that 1349 the removal-based mitigation strategies (MS1, MS2) are highly effective in reducing the usage of 1350 protected attributes in classification in just one mitigation round. 1351

Text	P(T)
"I like this city! There are many black people!"	0.00
"The homosexual marriage bill will be debated soon! I am in favor!"	0.00
"This city is incredibly modern! If you are gay, you are not judged."	0.16
"I hate this fucking shitty city! There are many black people!"	0.98

Fig. 11. The toxicity probability values P(T) for four sentences produced by the *mitigated* classifier (M_1^*) . The original model wrongly classified the first three sentences. Now, they are correctly classified.

i hate this fucking shitty city ! there are many black people !

Fig. 12. Words impacting the toxicity classification of the fourth sentence in Table 11. The more intense a word's red (blue) color, the more important the word contributes to toxic (non-toxic) classification.

D. Framework's running time analysis

The execution time to produce the mitigated training dataset depends on many factors. Given a
fixed model complexity, the execution times increase linearly with: (1) the unlabeled corpus size,
(2) the number of most important words annotated, and (3) the training dataset size. Increasing the
model's complexity results in a slight increase in the execution time of all components.

We report the execution time for the mitigation of the BERT model for the *nurse* occupation
classification (discussed in §5.4) with Integrated Gradients as the *Explainer* and ChatGPT-turbo-3.5
as the *Identifier*, using a single Nvidia RTX A6000 GPU. We used the test set as the unlabeled corpus,

containing approximately 98.3K sentences. Firstly, the Explainer uses the original classifier on each input text of the unlabeled corpus. With a batch size of 512, it takes 846 seconds (0.01 seconds per text). Then, the Explainer generates the explanations within each sentence for all the texts predicted with the nurse occupation, in this case 4,071, and aggregates the scores to compile the overall list of the most important words. This process is completed in 725 seconds (0.18 seconds per text). Next, the Identifier annotates the most important 400 words, running in 534 seconds (1.3 seconds per word). Finally, producing the mitigated training dataset with the word removal mitigation strategy (MS2) of the Moderator on the 255.7k examples in the training set requires 29 seconds. The total execution time is 2,134 seconds (35 minutes).

Our framework produces a mitigated training corpus, requiring an additional training phase to generate the mitigated model. The (re-)training time depends on the model's complexity and the original training data size. Some mitigation techniques (MS2, MS3, MS5) maintain the training dataset's dimensionality, resulting in equivalent training times for the mitigated and original models (1.5 hours in the previous example). In contrast, techniques like MS1 decrease or MS4 increase the dataset size, leading to corresponding changes in training time.
