

Interarm differences in systolic blood pressure and mortality among US army veterans: aetiological associations and risk prediction in the Vietnam experience study

James White¹, Laust H Mortensen², Mika Kivimäki³,
Catharine R Gale⁴ and G David Batty³

Abstract

Background: Differences between the arms in systolic blood pressure (SBP) of ≥ 10 mmHg have been associated with an increased risk of mortality in patients with hypertensive and chronic renal disease. For the first time, we examined these relationships in a non-clinical population.

Design: Cohort study.

Methods: Participants were 4419 men (mean age 38.37 years) from the Vietnam Experience Study. Bilateral SBP and diastolic BP (DBP), serum lipids, fasting glucose, erythrocyte sedimentation rate, metabolic syndrome, and ankle brachial index were assessed in 1986.

Results: Ten per cent of men had an interarm difference of ≥ 10 and 2.4% of ≥ 15 mmHg. A 15-year follow-up period gave rise to 246 deaths (64 from cardiovascular disease, CVD). Interarm differences of ≥ 10 mmHg were associated with an elevated risk of all-cause mortality (hazard ratio, HR, 1.49, 95% confidence interval, CI, 1.04–2.14) and CVD mortality (HR 1.93, 95% CI 1.01–3.69). After adjusting for SBP, DBP, lipids, fasting glucose, and erythrocyte sedimentation rate, associations between interarm differences of ≥ 10 mmHg and all-cause mortality (HR 1.35, 95% CI 0.94–1.95) and CVD mortality (1.62, 95% CI 0.84–3.14) were significantly attenuated.

Conclusions: In this non-clinical cohort study, interarm differences in SBP were not associated with mortality after accounting for traditional CVD risk factors. Interarm differences might not be valuable as an additional risk factor for mortality in populations with a low risk of CVD.

Introduction

A marked difference in systolic blood pressure (SBP) between the arms have been linked to subclavian stenosis,^{1,2} atherosclerotic plaque,³ and are most commonly observed in patients with hypertension,⁴ diabetes,⁵ and chronic renal disease,¹ suggesting interarm differences are a marker of peripheral vascular disease.⁶ The presence of an interarm difference has been linked to the delayed diagnosis⁷ and poor control of hypertension,⁸ and as such are recommended in screening guidelines on the assessment of hypertension.^{9,10} Despite these

associations, few cohorts record information on systolic blood pressure (SBP) in both arms and as a result associations with mortality are unclear. A small number of

studies have shown differences of ≥ 10 mmHg between the arms in SBP are associated with an increased risk for all-cause^{4,6} and cardiovascular disease (CVD) mortality in high risk patients (e.g. hypertension,^{4,11} chronic renal disease¹). However, owing to a paucity of data, the extent to which these results are apparent in non-clinical groups is unclear.

Accordingly, the aim of the present study was to examine whether interarm differences in SBP are associated with all-cause and CVD mortality over a 15-year follow-up period in a cohort of middle-aged men. In addition to examining the link, if any, between interarm differences in blood pressure and mortality, we also test whether incorporating information on interarm differences into an established risk score for CVD (the Framingham risk algorithm)¹² will improve its predictive capacity for all-cause and CVD mortality.

Methods

Study design and participants

Participants were drawn from the Vietnam Experience Study. The Vietnam Experience Study is a prospective cohort of US army veterans that was established in 1983 to compare the health of men who participated in the Vietnam war against those who did not.¹³ Briefly, on 31 December 1983, 18,313 men were drawn randomly from 5 million records of men who served in Vietnam and elsewhere. Of those men who were traced, 15,288 (85.6% response) participated in a telephone survey in 1985. A random sample was taken of telephone survey respondents in 1986 and 4462 (69.3% of those invited) attended a 3-day medical examination. Ethical approval for the study protocol was given by the US Office for Technology Assessment, the Department of Health and Human Sciences Advisory Committee, the Agent Orange Working Group Science Panel, and a review panel from the US Centers for Disease Control.

Assessment of interarm differences in blood pressure

Blood pressure was assessed after participants were seated for at least 2 minutes, with a standard mercury sphygmomanometer. Research nurses were instructed to ensure each arm was supported during measurements, free of clothing, and only to take measurements when men appeared relaxed and comfortable. Measurements were made twice in both arms in an alternating sequence: right arm, left arm, right arm, left arm. Standard or large cuffs were used as appropriate.¹⁴ Interarm differences in SBP were similar for the first (mean 1.00 mmHg; 95% CI 0.76–1.21) and second pair of assessments (1.05 mmHg, 95% CI 0.80–1.29).

Readings were averaged to obtain a mean SBP for each arm, which was then used to calculate an interarm difference (mean of right arm minus mean of left arm).

Assessment of risk factors for CVD mortality

Blood samples were taken in the morning after participants had fasted from 19:00 the previous day. Levels of triglycerides, cholesterol fractions, and urinary creatinine were ascertained using a Ektachem 700 AutoAnalyzer (Eastman Kodak, Rochester, New York). Serum glucose level was determined with an adaptation of the glucose oxidase-peroxidase-chromogen-coupled system for glucose determination in biological fluids. Erythrocyte sedimentation rate (ESR) was measured using the Westergren method. Height and weight were measured from which body mass index was calculated.

We defined the metabolic syndrome using a modified version of the Adult Treatment Panel III criteria (using body mass index ≥ 30 kg/m² instead of waist circumference, regarded by the WHO as an acceptable substitute).^{15,16} Diabetes status was defined as having a fasting plasma glucose ≥ 7.0 mmol/l and/or use of medication for diabetes.¹⁷

Hypertension was defined using the JNC 7 cut-off points for systolic/diastolic blood pressure $\geq 140/\geq 90$ mmHg, or use of antihypertensive medication.⁹ Men underwent a separate examination of the peripheral arterial system to calculate the ankle brachial index (ABI) using the Doppler technique. ABI for each leg was calculated by dividing the ankle systolic pressure by the higher of the right and left brachial systolic pressures obtained during this examination, and we used the lower of the left and right leg indices in the analysis, as an indicator of worse disease. Low ABI was defined as ABI ≤ 0.9 .¹⁸

Scores for the risk of coronary heart disease at 10 years were calculated using the Framingham equation with information on age, sex, total cholesterol levels, high-density lipoprotein (HDL) cholesterol levels, SBP, and smoking habits.¹²

Ascertainment of all-cause and CVD mortality

Information on deaths was collected for 15 years after the 1986 medical examination. Mortality was ascertained using databases supplied by the US army: the Veterans Administration (Beneficiary Identification and Records Locator Subsystem), the Social Security Administration, the Internal Revenue Service, and the National Center for Health Statistics (National Death Index). Events were defined as deaths from all-causes and those resulting from major CVD (ICD-9: 390–434, 436–448; ICD-10: I00–I78). A previous analysis found

the standardized (for age, race, and calendar year) mortality ratios of Vietnam Experience Study participants were comparable to those of an equivalent US male population.¹⁹

Statistical analysis

We compared participants' characteristics using ANOVA, chi-squared, and Kruskal–Wallis tests according to interarm differences in SBP of 0–4.9, 5–9.9, 10–14.9, and ≥ 15 mmHg. We examined the proportional hazards assumption graphically for each interarm difference in SBP with all-cause and CVD mortality and found no evidence for violation. We therefore used Weibull regression analysis to examine the association between interarm differences and mortality (for all causes and CVD). This model is a parametric form of the Cox proportional hazards model and accounts for the differing lengths of follow up among participants. This model also allows researchers to calculate the risk for mortality during a fixed period of time (t) as $r(t): 1 - \exp(-\exp^{(\log(t) - X\beta)/\sigma})$, where X is the vector of risk factors, β is the vector of coefficients, and σ is the estimated scale parameter. This model has been used previously in the Framingham Heart Study and to describe the effect of adding new risk factors for CVD to the Framingham risk score.²⁰

Interarm SBP difference was fitted as a continuous term (per 10 mmHg) and in separate models, using categories of <5 vs. ≥ 5 mmHg, <10 vs. ≥ 10 mmHg, and <15 vs. ≥ 15 mmHg. Hazard ratios and accompanying 95% CIs were sequentially adjusted for a series of potential confounding factors previously associated with peripheral vascular disease⁶ and CVD mortality.^{21,22} Adjustments were made for: obesity, smoking status, units of alcohol per week, and ethnic group (model 2); model 2 plus mean SBP and DBP (from the four measurements of SBP and DBP), metabolic syndrome, triglyceride, HDL cholesterol, glucose, ESR, and creatinine (model 3); model 3 plus ABI (≤ 0.9 vs. >0.9 ; model 4); and model 4 plus the Framingham risk score (model 5). We modelled an interaction between interarm differences at each cut-off point and hypertension status to examine whether associations were different in hypertensive men, as significant associations have been found in hypertensive patients before.^{4,11}

We also calculated the hazards for mortality using a Weibull model that included the Framingham risk score and interarm differences in SBP (at ≥ 5 , ≥ 10 , and ≥ 15 mmHg) and compared it to a model that only included the Framingham risk score. We examined discrimination across the two models by using Harell's c-index adjusted for optimism using 100 bootstrap repetitions,²³ an overall (likelihood ratio chi-squared

test) and penalized assessment of model fit (Akaike's Information Criterion,²⁴ and the Bayes Information Criterion).²⁵ We chose these measures of discrimination rather than the net reclassification improvement index,²⁶ as there was a low number of deaths in men with high Framingham risk scores.

We then estimated the effect on the hazard ratio of adjusting for a particular covariate using the following formula: [(HR adjusted for age and ethnicity – 1) – (HR adjusted for age and ethnicity plus covariate – 1)] / (HR adjusted for age and ethnicity – 1) \times 100. All analyses were performed with Stata version 11.0 using two-sided tests with a significance level of $p < 0.05$.

Results

Of the 4462 men eligible for inclusion, 4419 (99.03%) featured in the analytical sample. The 43 men who attended the medical examination but were excluded due to having missing values for some variables had a lower mean DBP (87.01 vs. 84.09 mmHg; $p = 0.04$) and ESR (41.63 vs. 36.90 mm/h; $p = 0.03$) but were similar in other respects. Supplementary Table 1 (available online) shows that relative to study members not selected for the medical examination, men included in the analytical sample were more likely to be obese (12.7 vs. 11.5%), but generally differences in characteristics between men included and excluded were small.

Table 1 shows the characteristics of the 4419 participants. A total of 1667 (37.7%) men had a mean interarm difference in SBP of ≥ 5 mmHg, 435 (9.8%) of ≥ 10 mmHg, 107 (2.4%) of ≥ 15 mmHg, and 24 (0.5%) of ≥ 20 mmHg. The mean interarm difference in SBP was 1.03 mmHg (95% CI 0.83–1.22), and was higher in the right arm. Interarm differences in SBP were positively associated with mean SBP (0–4.9 mmHg mean 122.7 vs. ≥ 15 mmHg mean 128.25; $p < 0.001$) and DBP (0–4.9 mmHg mean 83.79 vs. ≥ 15 mmHg mean 85.71; $p = 0.01$) and differences of 10 and 15 mmHg were more common in men with hypertension ($p < 0.001$), an ABI ≤ 0.9 ($p = 0.01$), and those who were obese ($p = 0.04$). There was, however, no evidence that interarm differences were associated with glucose levels or being defined as having diabetes or metabolic syndrome (Table 1).

A mean of 14.9 years of follow up (range 0.03–15.00) gave rise to 246 (5.60%) deaths in total of which 64 (26.01%) were due to CVD. Table 2 shows that in the unadjusted regression models, the hazard ratios for all-cause mortality among men with an interarm difference in SBP of >5 , >10 m and > 15 mmHg were 1.30 (95% CI 1.01–1.67), 1.49 (95% CI 1.04–2.14) and 1.37 (95% CI 0.68–2.77) respectively, with stronger associations apparent for CVD mortality: for >5 mmHg: HR 1.66, 95% CI 1.02–2.71; >10 mmHg: HR 1.93, 95%

Values are mean ± SD, median (interquartile range), or % (n); ^aOther group = Hispanics, Asians, Pacific Islanders, American Indians, and Alaskan Natives; ^bNormotensive: systolic blood pressure <140 mmHg and diastolic blood pressure <90 mmHg; hypertensive: systolic blood pressure >140 mmHg or diastolic blood pressure ≥90 mmHg or on hypertension medication (the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure criterion) or any hypertension medication; ^cFasting blood glucose ≥7.0 mmol/l or on medication for diabetes; ^dModified version of the Adult Treatment Panel III diagnostic criteria using body mass index ≥30 kg/m² instead of waist circumference; ^eBody mass index ≥30 kg/m²; HDL, high-density lipoprotein.

CI: 1.01–3.69; >15 mmHg HR 2.00, 95% CI 0.63–6.39. When interarm difference was fitted as a continuous term (per 10 mmHg), there was positive association with both all-cause (HR 1.13, 95% CI 1.01–1.27) and CVD mortality (HR 1.14, 95% CI 0.92–1.40) in the fully adjusted analysis (Supplementary Table 2).

Following adjustment for established risk factors for CVD, including the Framingham risk score, the adjusted hazard ratios (model 5) for interarm differences of >10 mmHg were significantly attenuated, with hazard ratios of 1.35 (95% CI=0.94–1.95) for all-cause and 1.62 (95% CI 0.84–3.14) for CVD mortality. Supplementary Table 3, shows separate adjustments for factors associated with lifestyle (smoking status, units of alcohol per week, obesity status) at the baseline assessment explained little of the attenuating effect on these associations. In general, adjustment for hypertension status (all-cause mortality 6–25%), metabolic syndrome (all-cause mortality 6–22%), and the Framingham risk score (all-cause mortality 16–33%) were associated with the largest percentage

reduction in associations between interarm differences and mortality.

Harrell's C-indices indicated a moderate level of discrimination but estimates were not significantly different across the Framingham risk scores and Framingham plus interarm difference models. There was also little change in the penalized measures of model fit between the Framingham risk scores and Framingham plus interarm difference models (Supplementary Table 4). Interactions between interarm differences at 5, 10, and 15 mmHg and hypertension status were also non-significant at each cut-off point for all-cause and CVD mortality (*p* > 0.05; data not tabulated).

Discussion

In a cohort of nearly 4500 men, an interarm difference in systolic blood pressure of 10 mmHg or more was associated with an increased risk for CVD and all-cause mortality. This association was, however, significantly

Values are hazard ratio (95% confidence interval). Reference category, interarm difference in systolic blood pressure < 5 , < 10 , or < 15 , depending on the analysis; Model 1, Unadjusted; Model 2, Model 1 + body mass index ≥ 30 kg/m², smoking status, alcohol intake (units per week), ethnic group; Model 3, Model 2 + systolic blood pressure, diastolic blood pressure, metabolic syndrome, triglycerides, HDL cholesterol, glucose, erythrocyte sedimentation rate; Model 4, Model 3 + ankle brachial index ≤ 0.9 ; Model 5, Model 4 + Framingham risk score.

attenuated after adjustment for established CVD risk factors. In regard to explanatory factors, smoking status, units of alcohol per week, and obesity played little or no part in the associations between interarm differences and mortality. ABI, a measure of peripheral artery disease, had a small but modest effect on the interarm difference–mortality association. Adjustment for hypertension, metabolic syndrome, and in particular Framingham risk scores at the baseline assessment had the strongest attenuating effects on the interarm difference – mortality association. Consistent with this finding, we found interarm differences did not improve upon the Framingham risk score in the prediction of mortality.

We identified one recent meta analysis⁶ and two cohort studies^{4,27} not included in the meta-analysis that examined the association between interarm differences in SBP and all-cause and CVD mortality in patients with hypertension⁴ and renal disease.²⁷ A positive association was reported in the meta analysis between all-cause mortality and an interarm difference of 10 mmHg or more in SBP (pooled HR for two

cohorts 1.90 (95% CI 0.8–4.7);^{8,11} and two cohorts not included in this meta analysis reported results of a similar magnitude.^{4,27} One cohort of hypertensive patients reported larger hazards for CVD than all-cause mortality after 5 (HR 2.8, 95% CI 0.9–9.2)¹¹ and 10 years of follow up (HR 4.2, 95% CI 1.7–10.8),^{2–4,7,12} with a similar pattern reported in a cross-sectional analysis of patients undergoing haemodialysis.²⁷ In contrast to these findings, we did not find an association between interarm differences in SBP and mortality. This inconsistency may in part be attributed to our deliberate selection of a low-risk cohort characterized by a comparatively low prevalence of hypertension, metabolic syndrome and other CVD risk factors. This resulted in a lower event rate and smaller interarm differences than have been reported in previous studies with hypertensive patients.^{4,11} In support of this assertion, we found a lower proportion of men with interarm differences at 10 mmHg or more (13.1 vs. 24.0%) and 15 mmHg or more (3.9 vs. 9.0%)⁴ and a lower proportion of deaths in the present cohort (all-cause mortality 5.4 vs. 25.7%).⁴

Despite these differences in sample characteristics, one study with hypertensive patients reported large hazard ratios for the interarm difference–mortality association even after adjusting for the Framingham risk score (difference of 10 mmHg in SBP: HR 2.2; 95% CI 1.4–3.6).⁴ This suggests a mechanism by which interarm differences increase the risk for mortality which does not involve factors included in the Framingham risk score; and that this factor was not present in our cohort. Interarm differences have been conceptualized, and are associated with a measure of peripheral artery disease, the ABI.^{1,2} However, we found a low ABI indicative of peripheral artery disease did not explain associations between interarm differences and mortality. It is therefore possible that the cut-off point we used on the ABI lacks predictive validity that or interarm differences are indicative of another comorbidity in hypertensive patients not adequately captured by traditional CVD risk factors.

The strengths of this study are its size, being larger than previous studies on interarm difference, and tracking of participants over a 15-year period. This allowed us to evaluate the prognostic value of interarm differences over a period in middle age where screening for hypertension typically starts. The non-clinical recruitment meant we could examine associations in a low-risk population for the first time and the comprehensive measurement of CVD risk factors allowed us to address concerns that interarm differences might not add anything over routine CVD risk factor assessment.

This study is not, however, without limitations. First, the sequential method of recording blood pressure we used may have produced larger interarm differences than simultaneous readings.^{28,29} Although, little difference has been found between these methods in estimates of the association of interarm differences with ABI, or all-cause mortality.⁶ Second, we did not have data on women, and all investigations to date have been in cohorts in middle to old age;^{1,4,8,11,27} thus, further testing is needed to confirm associations in women and different age groups. It is also worth noting that despite not adding to the prediction of mortality, assessment of blood pressure in both arms may have clinical value by increasing the sensitivity of diagnosis and management of hypertension through the use of measurements from the arm with the highest reading. Additional studies, ideally a controlled clinical trial, are needed to assess whether incorporating bi-lateral brachial assessments into screening for hypertension in primary care, would improve the identification and management of individuals at risk for a coronary heart disease event.

In conclusion, we found that interarm differences were associated with survival over a 15-year period in men with a low risk of CVD, but that these associations

were explained, in part, by traditional CVD risk factors. As these risk factors are already part of routine CVD risk screening, interarm differences may not offer anything over established risk prediction algorithms, such as the Framingham risk score, in the prediction of mortality in populations with a low risk of CVD.

Funding

This work was supported by the Centre for the Development and Evaluation of Complex Interventions for Public Health Improvement (by Dr White), a UKCRC Public Health Research: Centre of Excellence. Funding from the British Heart Foundation, Cancer Research UK, Economic and Social Research Council (ESRC RES-590-28-0005), Medical Research Council, the Welsh Assembly Government and the Wellcome Trust (WT087640MA), under the auspices of the UK Clinical Research Collaboration, is gratefully acknowledged. MK is supported by the MRC and by a professorial fellowship from the ESRC. CG and GDB are supported by the Centre for Cognitive Ageing and Cognitive Epidemiology, Department of Psychology, which is funded by the Biotechnology Sciences Research Council, the Engineering and Physical Sciences Research Council, the Economic and Social Research Council, the Medical Research Council and the University of Edinburgh as part of the cross-council Lifelong Health and Wellbeing initiative. The funding organizations played no role in the design and conduct of the study; collection, management, analysis and interpretation of the data; and preparation, review or approval of the manuscript. Dr. White had full access to all the data in the study and takes responsibility for the integrity of the data and accuracy of the analysis.
