## ABSTRACT

A comprehensive hot line list is calculated for  $^{31}\text{PH}_3$  in its ground electronic state. This line list, called SAITY, contains almost 16.8 billion transitions between 7.5 million energy levels and it is suitable for simulating spectra up to temperatures of 1500 K. It covers wavelengths longer than  $1\ \mu\text{m}$  and includes all transitions to upper states with energies below  $hc \times 18\,000\ \text{cm}^{-1}$  and rotational excitation up to  $J = 46$ . The line list is computed by variational solution of the Schrödinger equation for the rotation–vibration motion employing the nuclear-motion program TROVE. A previously reported ab initio dipole moment surface is used as well as an updated ‘spectroscopic’ potential energy surface, obtained by refining an existing ab initio surface through least-squares fitting to the experimentally derived energies. Detailed comparisons with other available sources of phosphine transitions confirms SAITY’s accuracy and illustrates the incompleteness of previous experimental and theoretical compilations for temperatures above 300 K. Atmospheric models are expected to severely underestimate the abundance of phosphine in disequilibrium environments, and it is predicted that phosphine will be detectable in the upper troposphere of many substellar objects. This list is suitable for modelling atmospheres of many astrophysical environments, namely carbon stars, Y dwarfs, T dwarfs, hot Jupiters and Solar system gas giant planets. It is available in full from the Strasbourg data centre, CDS, and at [www.exomol.com](http://www.exomol.com).

**Key words:** molecular data – opacity – astronomical data bases: miscellaneous – planets and satellites: atmospheres – brown dwarfs – stars: low-mass.

## 1 INTRODUCTION

Over the past 20 years, discoveries of planets, stars and substellar objects have demonstrated the enormous diversity of astrophysical bodies in the Universe. Thanks to modern techniques and technology, it is now possible to study the atmospheres of these objects and retrieve some knowledge of their composition, structure and dynamics. However, these are extremely complex systems to model and accurate observations are still difficult to perform. In particular, it is crucial for the correct characterization of these atmospheres that complete and accurate descriptions of the molecules that comprise them are available. Here phosphine, or  $\text{PH}_3$ , is considered.

Phosphorus is the one of the most abundant chemically reactive volatile elements in a solar type system (with S, after H, C, N and O). Although phosphorus has considerably smaller cosmic abundances than H, O, C or N, it is predicted to have an important role in atmospheric chemistry and dynamics. Phosphorus is not particularly common in the universe but it is ubiquitous and is important for most

essential biochemical functions. Due to its role as biogenic particle, phosphorus could potentially be used in the search for extinct or extant life in other planets (Maciá 2005).

A large fraction of the existing phosphorus in various astronomical environments is expected to be found in the form of phosphine, or  $\text{PH}_3$  (Visscher, Lodders & Fegley Jr 2006; Agundez et al. 2014). Phosphine is an extremely toxic, semirigid, relatively stable, oblate, symmetric-top molecule, and has so far been detected in the lower troposphere of the Earth, the atmospheres of Jupiter and Saturn and in the carbon star envelope IRC 10216 (Prinn & Lewis 1975; Tarrago et al. 1992; Edgington et al. 1998; Fletcher et al. 2009; Agundez et al. 2014).

Partially due to the lack of strong absorption from  $\text{CH}_4$ , the  $5\ \mu\text{m}$  spectral window is a region of low opacity in Jupiter, Saturn and the Earth’s atmosphere. Alongside other molecules ( $\text{CO}$ ,  $\text{GeH}_4$ ,  $\text{AsH}_3$ ),  $\text{PH}_3$  is partly responsible for the continuum opacity in this region and has detectable absorption bands (Noll & Marley 1997), specifically the  $2\nu_2$  overtone bending band. In Jupiter, phosphorus is found at approximately tropospheric solar abundances (1.1 ppm) in the form of phosphine, and is over four times more abundant in Saturn (4.5 ppm), also as phosphine (Noll & Marley 1997;

<sup>★</sup>E-mail: [clarasousasilva@gmail.com](mailto:clarasousasilva@gmail.com)

Owen & Encrenaz 2003; Visscher et al. 2006; Moreno, Marten & Lellouch 2009). This agrees with models of core accretion that expect Saturn to have a considerably larger fraction of ice to gas than Jupiter. In both planets, this abundance of a disequilibrium species like phosphine at observable levels of the atmosphere reflects both a large reservoir in deep regions of the planets and the strength of the convective transport of the molecule.

In local thermochemical equilibrium (LTE),  $P_4O_6$  would be expected to dominate the upper atmospheres of planets with approximate solar abundances. However, almost no  $P_4O_6$  is found in these environments because phosphine quenching and rapid vertical mixing from regions where  $PH_3$  is dominant leads to high disequilibrium abundances. This quenching occurs because time-scales for the conversion of  $PH_3$  to  $P_4O_6$  are much larger than the convective time-scales, so the production of  $P_4O_6$  is kinetically inhibited (Fegley & Lodders 1996; Visscher et al. 2006; Moses 2014). Disequilibrium chemistry is expected to lead to phosphine being orders of magnitude more abundant than predicted by equilibrium models, both for environments where  $T \geq 2000$  K and at the uppermost atmosphere of most substellar objects (Moses 2014).

The thermal decomposition of phosphine at high temperatures has been studied for a long time, starting with Hinshelwood & Topley (1924). Recently Visscher et al. (2006) discussed at length the pressure and temperature parameters at which phosphine is expected to be found in solar composition and LTE environments. At 1 bar, phosphine is predicted to be a dominant phosphorus carrying molecule in environments with temperatures up to about 1500 K, and it is expected to contribute to the composition of atmospheres up to about 2500 K if the pressure is above 3 bar.

The detection of phosphine can therefore be used as a chemical probe for deep layers of both Jupiter and Saturn's atmosphere, as it is only present at the top layers through vertical mixing. Analysis of future observations of Jupiter from NASA's TEXES, NASA's *Juno* and ESA's *JUICE* will require accurate data on phosphine, and past observations of Saturn from *Cassini/VIMS* and *Cassini/CIRS* will gain from further understanding its spectrum (Fletcher et al. 2009; Encrenaz et al. 2014). Suspected inaccuracies found in regions of the existing phosphine data may be behind misinterpretation of previous astronomical data (Malathy Devi et al. 2014). Additionally, *Juno* will cover the full latitude and longitude of Jupiter and its analysis of the polar atmosphere of Jupiter should confirm a depletion of phosphine in the polar vortices analogous to Saturn's (Fletcher et al. 2009). Titan has also been predicted to contain phosphine, but spectrum recorded with *Cassini/CIRS* failed to detect any, putting an upper limit of 1 ppb on the phosphine abundance of its atmosphere (Nixon et al. 2013). Similar unsuccessful detections of phosphine in Neptune and Uranus suggest that the abundance of phosphorus on these planets is subsolar (Moreno et al. 2009), with an upper limit of 0.1 times solar P/H abundance.

The existence of phosphine outside the Solar system has recently been confirmed by Agundez et al. (2014) in the carbon star envelope IRC 10216, with an abundance of  $10^{-8}$  relative to  $H_2$ . This was done using the HIFI instrument on board *Herschel*. Together with HCP,  $PH_3$  is one of the major phosphorus carriers in the inner circumstellar regions.

There have been multiple predictions of phosphine in many other astrophysical environments, but its presence and formation scenarios remain poorly understood and none has been found outside the Solar system other than the aforementioned discovery of circumstellar phosphine in IRC 10216. This is due to a variety of factors, including the sparsity of fundamental data which this work is rec-

tifying. Below are some of the expectations for further phosphine detection.

A particular region of interest is the 4.1–5.1  $\mu m$  window, which is found to be an interval of very low opacities in both Jupiter and Saturn. It is therefore expected that detection of  $PH_3$  in this region could be used as a marker for vertical convection and a tracer for tropospheric dynamics in the upper atmospheres of other astronomical bodies, namely hot Jupiters and brown dwarfs.

In Y dwarfs, with  $T_{\text{eff}} \approx 500$  K, phosphine should exhibit a strong feature in the mid-infrared at 4.3  $\mu m$  (Morley et al. 2014), where it is predicted to be the dominant source of opacity. T dwarfs, with  $T_{\text{eff}} \leq 1300$  K, will mostly be dominated by other molecules (e.g.  $H_2$ ,  $NH_3$ ,  $CH_4$ ,  $CO$ ,  $H_2O$  and  $CO_2$ ) but phosphine can still have a significant contribution to the shape of the spectrum. The NIRSpec near-infrared spectrograph on *JWST* will be able to collect spectra in the 2.9–5  $\mu m$  region with sufficient sensitivity to detect the presence or absence of phosphine, particularly for slightly cooler Y dwarfs with  $T_{\text{eff}} \leq 450$  K (Morley et al. 2014).

Phosphine is predicted to be the dominant phosphorus molecule in cool T dwarfs like Gliese 229B where it is expected to carry all the phosphorus in the atmosphere to the top layers, with approximately 0.6 ppm.  $PH_3$  should be detectable (for resolutions higher than  $1.2 \text{ cm}^{-1}$ ) in the 4.45–5.40  $\mu m$  spectral window of Gliese 229B, particularly the 4.3  $\mu m$  feature (Fegley & Lodders 1996; Noll & Marley 1997). Models estimate that, for regions where  $T \geq 1155$  K, the major phosphorus carrying gas in Gliese 229B is phosphine, with rapid vertical mixing quenching its destruction (Fegley & Lodders 1996). As the temperature rises,  $PH_3$  is converted to  $P_4O_6$ , but it should still be present at observable heights.

In hotter environments, like HD209458b and L dwarfs, where phosphorus equilibrium chemistry is approached, the phosphine abundances decrease significantly to about 50 ppb (Visscher et al. 2006). It is still possible to detect phosphine in these atmospheres, but higher resolution is required to distinguish its features from that of neighbouring CO bands (Noll & Marley 1997). However, phosphine is expected to be the dominant phosphorus carrying species at the observable atmosphere of hot T dwarfs and cool L dwarfs, with effective temperatures between 1000 and 1400 K (Visscher et al. 2006).

There are still disequilibrium effects that are not completely understood. For example, observations of Saturn's upper troposphere found that phosphine abundances decreased with depth (Malathy Devi et al. 2014), contradicting the proposal that phosphine is dredged up through vertical mixing from deeper layers of the atmosphere. This depletion is not understood, as there is no known formation mechanism for phosphine at the upper levels of Saturn's atmosphere that could lead to the abundances observed. Suggested explanations for this inconsistency are a poor understanding of the aerosol opacity in the VIMS observations and intensity uncertainties in the molecular data.

Future detections of phosphine can only be achieved by accurately modelling these atmospheres. This requires an extensive knowledge of the temperature-dependent spectrum of phosphine, which can only be established with a comprehensive line list.

There are multiple sources of phosphine data (Loomis & Strandberg 1951; Helminger & Gordy 1969; Davies et al. 1971; Chu & Oka 1974; Helms & Gordy 1977; Baldacci et al. 1980; Belov et al. 1981; Pickett, Poynter & Cohen 1981; Tarrago, Dang-Nhu & Goldman 1981; Tarrago et al. 1992; Ainetschian et al. 1997; Fusina & Di Lonardo 2000; Wang, Shi & Zhu 2000; He et al. 2001; Brown et al. 2002; Suarez 2002; Ulenikov et al. 2002, 2004; Yurchenko et al. 2003, 2005b, 2006, Salem et al. 2004; Wang et al. 2005;

Butler et al. 2006; Cazzoli & Pazzarini 2006; Temma et al. 2006; Kshirsagar 2007; Ovsyannikov et al. 2008a,b; Nikitin et al. 2009; Müller 2013), both experimental and theoretical, which are further described in our previous paper on room temperature phosphine (Sousa-Silva, Yurchenko & Tennyson 2013). Additionally, a recent paper by Malathy Devi et al. (2014) improved the experimental phosphine spectrum for the 4.08–5.13  $\mu\text{m}$  region, which, as mentioned above, is of particular importance due to it being an interval of low opacity in gas giants and brown dwarfs (Noll & Marley 1997). Most of these experimental sources have already been incorporated in the HITRAN data base (Rothman et al. 2013) and collectively contain less than 30 000 lines, and no wavelength coverage shorter than 2.7  $\mu\text{m}$ .

Despite these efforts, no complete line list for hot phosphine exists in the literature. The line lists mentioned above only cover low values of rotational excitations, a small number of bands, and some regions are missing altogether. Often, contamination of gas samples affects the measured intensities (Malathy Devi et al. 2014), and this can be an effect that is hard to accurately compensate for. It is not unusual for experimental data with extremely accurate line positions to have intensity uncertainties well above 10 per cent. Additionally, all the experimental data sets mentioned above are designed to be used only at room temperature and below. Consequently, they are insufficiently complete to be appropriate for use in the characterization of atmospheres of any astronomical bodies at higher temperatures.

A theoretical line list for phosphine was previously computed by us (Sousa-Silva et al. 2013), henceforth SYT. However, although SYT contains many orders of magnitude more lines than any previous phosphine line list (137 million transitions between 5.6 million energy levels), it too was only designed to be accurate for temperatures below 300 K, making it unsuitable for most astronomical studies. Since HITEMP (Rothman et al. 2010), HITRAN’s high-temperature data base, does not include phosphine, SAIITY is the first line list suitable for modelling phosphine spectra in environments up to 1500 K. The completeness and coverage of the SAIITY line list makes it particularly suitable for studies of non-LTE environments.

The current work is performed as part of the ExoMol project. This project aims to provide line lists of spectroscopic transitions for key molecular species which are likely to be important in the atmospheres of extrasolar planets and cool stars; its aims, scope and methodology are summarized in Tennyson & Yurchenko (2012). The SAIITY line list builds on previously released ones for polyatomic hydrides such as water (Barber et al. 2006), ammonia (Yurchenko, Barber & Tennyson 2011), formaldehyde (Al-Rafaie et al. 2014) and methane (Yurchenko & Tennyson 2014; Yurchenko et al. 2014). Finally we note that energy levels generated for this work have been used as part of a study to compute thermodynamic properties of phosphine and ammonia, including its partition function, for temperatures up to 6000 K (Sousa-Silva et al. 2014).

## 2 OVERVIEW OF THE SAIITY LINE LIST

In the following  $\text{PH}_3$  and phosphine will refer to the main isotopologue  $^{31}\text{PH}_3$ , since  $^{31}\text{P}$  is the only non-synthetic, stable isotope of phosphorus.

SAIITY is a catalogue of transitions, each characterized by a frequency, its lower and upper energy level, Einstein coefficient and quantum numbers. Together these fully describe the spectrum of the phosphine molecule within the frequency range 0–10 000  $\text{cm}^{-1}$ , or wavelengths longer than 1  $\mu\text{m}$ . It contains 16 803 703 395 transi-

tions between 7510 823 energy levels below 18 000  $\text{cm}^{-1}$ , with rotational quantum number  $J$  values up to 46. The highest energy state considered is 18 000  $\text{cm}^{-1}$  above the zero-point energy (5213.9280  $\text{cm}^{-1}$ ) for phosphine, as the intensity of transitions to higher energy levels is too weak to be important, even at temperatures of 1500 K. Consequently, to ensure that the line list is complete within the frequency range 0–10 000  $\text{cm}^{-1}$ , the highest lower energy state considered is 8000  $\text{cm}^{-1}$ . All transitions are within the ground electronic state of phosphine, since the first excited electronic state is above the dissociation limit of the molecule.

The strongest SAIITY transition has an Einstein  $A$  coefficient of 89.1  $\text{s}^{-1}$  while the weakest lines go down to  $10^{-48} \text{s}^{-1}$ . In non-LTE environments even extremely weak lines can play an important role in the shape of a spectrum. This is the reason behind including transitions with extremely weak absorptions in SAIITY.

The final line list is presented in the ExoMol format (Tennyson, Hill & Yurchenko 2013), with a transition file ordered in increasing transition frequency and an energy file. The former contains a description of each transition by its upper (final) and lower (initial) energy level reference numbers ( $f$  and  $i$ ), as well as the electric dipole transition probability represented as an Einstein coefficient  $A_{if}$  in  $\text{s}^{-1}$ . Using this information, the line intensity of each transition can be calculated for any given temperature. The latter connects each index with the description of the corresponding energy level. Each energy level is described by the quantum numbers associated with the molecular group symmetry (Bunker & Jensen 1998),  $C_{3v}(\text{M})$  for  $\text{PH}_3$  and total angular momentum  $J$ . The quantum numbers for  $\text{XY}_3$  molecules are quite complicated and have recently been discussed in detail for ammonia by Down et al. (2013). Our  $\text{PH}_3$  quantum numbers follow the same general principles but are somewhat simpler since we neglect the possibility of a tunnelling mode.

Each energy level is described by the following quantum numbers :

$$n_1, n_2, n_3, n_4, L_3, L_4, L, \Gamma_{\text{vib}}, J, K, \Gamma_{\text{rot}}, \Gamma_{\text{tot}}, \quad (1)$$

where  $L_3 = |l_3|$ ,  $L_4 = |l_4|$ ,  $L = |l|$ ,  $K = |k|$ . Here the vibrational quantum numbers  $n_1$  (symmetric stretch),  $n_2$  (symmetric bend),  $n_3$  (asymmetric stretch) and  $n_4$  (asymmetric bend) correspond to excitations of, respectively, the  $\nu_1$ ,  $\nu_2$ ,  $\nu_3$  and  $\nu_4$  modes. The doubly degenerate modes  $\nu_3$  and  $\nu_4$  require additional quantum numbers  $L_3 = |l_3|$  and  $L_4 = |l_4|$  describing the projections of the corresponding angular momenta (see Bunker & Jensen 1998). The vibrational quantum number  $L = |l|$ , characterizes the coupling of  $l_3$  and  $l_4$ . The projection of the total vibrational angular momentum  $L$  is included to reduce ambiguity in the description of the energy levels, as it was in SYT (Sousa-Silva et al. 2013).  $\Gamma_{\text{rot}}$ ,  $\Gamma_{\text{vib}}$  and  $\Gamma_{\text{tot}}$  are, respectively, the symmetry species of the rotational, vibrational and total internal wavefunctions in the molecular symmetry group  $C_{3v}(\text{M})$ , spanning  $A_1$ ,  $A_2$  and  $E$ , where  $E$  is two-fold degenerate.  $J$  is the total angular momentum and  $K = |k|$ ,  $k = -J, \dots, J$  is the projection of the total angular momentum on the molecule fixed axis  $z$ . These 12 quantum numbers reduce ambiguity to the assignment of the energy levels. However, only  $J$  and  $\Gamma_{\text{vib}}$  are rigorous; at higher energies, energy states cannot necessarily be assigned unambiguous quantum labels. Apart from the quantum numbers we also provide the largest eigenco-efficient used to produce the theoretical assignment, see, for example, Yurchenko & Tennyson (2014).

Since  $\text{PH}_3$  transitions obey the strict selection rules  $A_1 \leftrightarrow A_2$ ,  $E \leftrightarrow E$ , and  $\Delta J = 0, \pm 1$ , no higher  $J$  values were considered because  $J = 45$  is the highest value of  $J$  for which there are eigenvalues

Column	Notation
--------	----------

1	$N$	Energy level reference number (row)
2	$\bar{E}$	Term value (in $\text{cm}^{-1}$ )
3	$g_{\text{tot}}$	Total degeneracy
4	$J$	Rotational quantum number
5	$\Gamma_{\text{tot}}$	Total symmetry in $C_{3v}(\text{M})$
6	$K$	Rotational quantum number, projection of $J$ on to the $z$ -axis
7	$\Gamma_{\text{rot}}$	Symmetry of the rotational contribution in $C_{3v}(\text{M})$
8	$L$	The projection of the total vibrational angular momentum
9,10,11,12	$n_1-n_4$	Normal mode vibrational quantum numbers
13,14	$L_3, L_4$	Projections of the angular momenta corresponding to $n_3$ and $n_4$
15	$\Gamma_{\text{vib}}$	Symmetry of the vibrational contribution in $C_{3v}(\text{M})$
16	$ C_i ^2$	Largest contribution used in the assignment
17,18,19,20,21,22	$s_1, s_2, s_3, b_1, b_2, b_3$	Local mode vibrational quantum numbers

existing below  $8000 \text{ cm}^{-1}$ , which is the highest lower energy threshold used in SAITY.

Excerpts from the energy and transition files are given in Tables 1 and 2, respectively, with seven additional columns giv-

ing TROVE quantum numbers which are described in the supplementary data and by Sousa-Silva et al. (2013). As per the ExoMol convention, these are named SAITY.transitions and SAITY.states. The complete line list is freely available and

can be downloaded from the Strasbourg data centre, CDS, via <ftp://cdsarc.u-strasbg.fr/pub/cats/J/MNRAS/> or from the ExoMol website, [www.exomol.com](http://www.exomol.com). The website also offers the opportunity to download cross-sections (Hill, Yurchenko & Tennyson 2013).

### 3 BACKGROUND TO THE CALCULATION

For this calculation we used a slightly refined version of the potential energy surface (PES) used for the SYT line list by Sousa-Silva et al. (2013). This refinement was necessary because in our semi-empirical approach the refined PESs are ‘effective’ surfaces, inextricably connected to the size of the basis set. To achieve the accuracy and degree of completeness required of the SAITY line list, the present calculations used an increased basis set, so a refinement of the surface was necessary. It was done by performing a least-squares fit to available experimental rovibrational energies of  $\text{PH}_3$  with the rotational quantum numbers  $J = 0, 1, 2, 3, 4$ , mostly taken from the HITRAN data base.

The PES parameters used here are given as Supplementary Material to this paper in the form of a FORTRAN 95 program. It should be noted that this is also an ‘effective’ PES and guarantees to give accurate results only in conjunction with the same method and basis set used to produce it with.

As with the SYT  $\text{PH}_3$  line list, the variational rotation–vibration program suite TROVE (Yurchenko, Thiel & Jensen 2007) was employed for all nuclear motion calculations for SAITY. The application of variational methods to polyatomic molecules requires increasingly large Hamiltonian matrices to be diagonalized, which is very computationally demanding and until recently prohibitively so. With the power and parallelism of modern computers, it is now possible to use this method for the production of accurate spectra.

To accommodate the higher demands of the present line list, a larger basis set was used, with a corresponding higher polyad number. The polyad number controls the size of the basis sets at all contraction steps using the polyad-truncation scheme (Ovsyannikov et al. 2008b), defined by

$$P = 2(s_1 + s_2 + s_3) + b_1 + b_2 + b_3 \leq P_{\max}, \quad (2)$$

where  $s_i$  and  $b_i$  are the primitive quantum numbers associated with the basis functions,  $\phi_{s_i}$  and  $\phi_{b_i}$ , for the stretching modes and the bending modes, respectively. Here TROVE (Yurchenko et al. 2007) constructs a synthetic line list for  $^{31}\text{PH}_3$  in its ground electronic state. To this end, the Schrödinger equation for the rotation–vibration motion of nuclei is solved to obtain eigenvalues (rovibrational energies) and eigenfunctions (nuclear motion wavefunctions). The latter are necessary for rovibrational averaging of the dipole moment of the rotating molecule and thus to compute the transitional probabilities, usually expressed in terms of the Einstein coefficients or line strengths following the description by Yurchenko et al. (2005a). Our basis set contains two contributions: (i) all basis functions with the primitive quantum numbers satisfying  $P \leq 16$  and (ii) stretching functions ranging up to  $P = 20$  but with some high  $P$ -polyad ( $P \geq 17$ ) stretching contributions that couple all three stretching modes removed. Increasing the polyad number is computationally costly, and as such the increased coverage of the stretching excitations only was motivated by assumption that the stretching excitations produce the strongest transitions. The larger basis set guarantees a better convergence for the present calculations, but requires the PES to be refined to the new basis set, as discussed above. The  $J = 0$  Hamiltonian matrices were then constructed, and the empirical basis set correction scheme (EBSC) of Yurchenko et al. (2009) was applied. Here, band centre values from the rovibrational calculations are replaced with extremely accurate corresponding experimental values, or deviated towards these values. This is performed iteratively, until the entire band is considered to be optimal. At the end of this correction, the rms deviation for the bands whose centre had been replaced went from an rms deviation of  $0.02 \text{ cm}^{-1}$  in SYT to  $0.012 \text{ cm}^{-1}$  in SAITY. This improvement may reflect the better use of EBSC, but overwhelmingly is due to the use of the enhanced PES. Table 3 gives a band-by-band summary of this improvement. The  $2\nu_4$  and  $\nu_2 + \nu_4$  bands were particularly responsive to this process. Further details of the TROVE computational procedure are given by Sousa-Silva et al. (2013).

Table 3 also compares the integrated band intensity computed for the SYT and SAITY line lists with those obtained from HITRAN 2012. In each case, the band intensity was computed by explicit summation of the intensities at 296 K of all lines within a band. The two  $2\nu_4$  bands were considered together since it is difficult to disentangle their transitions. The band intensities for the two computed lists are very similar. They are both in reasonable agreement with, but somewhat larger than, HITRAN; given the greater completeness of the computed line lists, it is to be expected that this method would yield somewhat larger band intensities.

For the rotational spectra from the Cologne Database for Molecular Spectroscopy (CDMS) the integrated intensity is  $1.214 \times 10^{-18} \text{ cm/molecule}$  which is very similar to SAITY’s  $1.218 \times 10^{-18}$ . One further test on the intensities was performed. Given that the intensity of weak lines can be highly sensitive to the choice of wavefunction (Tennyson 2014), and hence the underlying PES, an explicit comparison was made between SYT and SAITY of the intensities of the weak, forbidden lines with  $\Delta K = 3$ . These were found to be very little changed for the individual transitions inspected, with the integrated intensity for all these transitions going from  $5.53 \times 10^{-19} \text{ cm/molecule}$  in SYT to  $5.60 \times 10^{-19} \text{ cm/molecule}$  in SAITY. In practice variational procedures, such as those used here, have long been used to get reliable predicted intensities for such transitions (Miller, Tennyson & Sutcliffe 1990; Lodi & Tennyson 2008).

As well as employing a larger basis set than before, this line list extends SYT by using (i) a larger energy level range of  $E_{\max}$

**Table 3.** Observed bands centres, from HITRAN (Rothman et al. 2013), and standard deviation,  $\sigma$ , with which the TROVE calculations reproduce the terms within each band. The first three columns give integrated band intensity for SYT, SAITY and HITRAN.

Band	Band centre ( $\text{cm}^{-1}$ )	$\sigma$ ( $\text{cm}^{-1}$ )		Band intensity ( $\text{cm} / \text{molecule}$ )

**Figure 1.** Dimensions of the  $E$ -symmetry matrices with  $J$  (blue diamonds), the corresponding number of eigenvalues below  $18\,000\text{ cm}^{-1}$  (red circles) and number of non-zero elements on each row (green squares).

$\leq 18\,000\text{ cm}^{-1}$  (instead of  $\leq 12\,000\text{ cm}^{-1}$ ), (ii) wider frequency range of  $0\text{--}10\,000\text{ cm}^{-1}$  (instead of  $0\text{--}8000\text{ cm}^{-1}$ ) and (iii) rotational excitations considered up to  $J_{\text{max}} = 46$  (instead of 34). This expansion is necessary to guarantee accuracy and completeness at high temperatures, but it makes the calculation of the line list much more computationally demanding.

The diagonalization of the matrices involved in the variational procedure corresponding to high values of  $J$  is the most computationally demanding part of a line list calculation, as it requires substantial memory, long runs and requires MPI to diagonalize efficiently. A variety of strategies were used to deal with this. The dimension of the matrices of the symmetries scales approximately as 1:1:2, for  $A_1$ ,  $A_2$  and  $E$ , respectively.

The largest matrix to be diagonalized for SAITY ( $J = 46$ ,  $E$  symmetry) has dimensions of 444 726. As can be seen from Fig. 1, the size of the rovibrational matrices scales linearly with  $J$ , but the number of non-zero elements and the number of eigenvalues under the energy threshold for the line list ( $8000\text{ cm}^{-1}$ ) do not. The size of the matrices grows roughly with  $N_{J=0}^\Gamma \times (2J + 1)$ , where  $N_{J=0}^\Gamma$  is the dimension of the matrix block for  $J = 0$ . For the symmetry with the biggest matrices,  $\Gamma = E$ ,  $N_{J=0}^E = 4778$ .

The initial (low  $J$ ) matrices were sufficiently small to employ the standard LAPACK eigensolver DSYEV (Anderson et al. 1999) to solve the full eigenvalue problem, and this was used for all  $J \leq 16$  and 9 ( $A$  and  $E$  symmetries, respectively). As the matrices increased in size, memory constraints required the MPI version PDSYEV of this

eigensolver to be used on large shared memory systems (COSMOS) in order to cope with the size of these matrices. We also successfully explored the openmp PLASMA library (Kurzak et al. 2013) for the matrices with dimensions between 100 000 and 200 000.

Using these three eigensolvers, all eigenvalues and eigenvectors were computed for  $J \leq 46$ , using the energy threshold of  $18\,000\text{ cm}^{-1}$ , totalling 7510 823 energy levels.

A high-quality dipole moment surface (DMS) is a prerequisite for correctly computing the transition moments used to generate the Einstein  $A$  coefficients and in turn accurate line intensities; Tennyson (2014) gives a discussion of the issues involved in this. The DMS used here is completely theoretical, an approach that has been shown to yield results competitive with experiment (Lynas-Gray, Miller & Tennyson 1995), and has already been used in the SYT line list where it provided intensities in good agreement with experiment. It is a six-dimensional ab initio (CCSD(T)/aug-cc-pVTZ) electric DMS, calculated on a grid of 10 080 molecular geometries, and it is described in further detail elsewhere (Yurchenko et al. 2006). To reduce the size of the computation, only eigencoefficients of the upper states with a magnitude larger than  $10^{-14}$  were selected.

Despite matrix diagonalization utilizing the most computational resources, it is the computation of transition intensities that actually dominates the total computer time. However this step has the advantage that it is easily parallelized and spread over many processors, and indeed computer systems. As shown in Fig. 2, the number of transitions between energy levels peaks between  $J = 15$  and 18, so this was the region that corresponded to the most expensive part of the intensity calculations, accounting for about 17 per cent of the total transitions. The number of transitions does not correlate smoothly with  $J$  pairs due to the different way  $A$  and  $E$  symmetries are affected by  $J$ , particularly for values of  $K$  that are multiples of 3.

Employing CPUs available to us at the High Performance Computing (HPC) centres DiRAC@Darwin and DiRAC@COSMOS, TROVE was used to calculate the intensities across almost all symmetries and  $J$  values. However, this proved slow and computationally expensive, so for some of the particularly computationally demanding sections, a newly-developed graphical processor unit (GPU) implementation of the TROVE program was employed. This allowed us to use multiple GPUs to compute multiple initial states simultaneously, effectively reducing computing time by over an order of magnitude. This was used to compute the absolute intensities for most  $A$  symmetry transitions with  $J \geq 20$ , on the Emerald cluster.

**Figure 2.** Number of energy levels in each rotational quantum number,  $J$ , and transitions between  $J$  and  $J + 1$  in the SAIITY line list, summed over all symmetries.

The algorithm employed will be described elsewhere (Al-Refaie, Yurchenko & Tennyson 2015).

After this work was completed, Nikitin, Rey & Tyuterev (2014) published a detailed analysis of ab initio methods for calculating the phosphine DMS. In general the agreement between their predictions and ours is very good.

#### 4 LINE LIST VALIDATION AND TEMPERATURE DEPENDENCE

Line lists do not specify a temperature, since the Einstein coefficients for the transitions are independent of temperature. SAIITY can only be considered a ‘hot’ line list because its energy and rotational excitation thresholds ensure that all those states that are significantly populated up to  $T = T_{\max}$  are used to produce the catalogue of transitions.

To model the spectrum of phosphine at different temperatures, the line intensities are calculated using

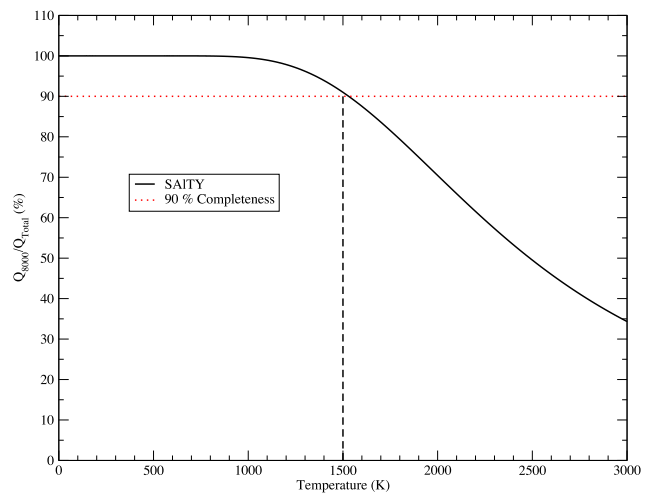

$$I(f \leftarrow i) = \frac{A_{if}}{8\pi c} g_{ns}(2J_f + 1) \frac{\exp\left(-\frac{E_i}{kT}\right)}{Q \tilde{\nu}_{if}^2} \left[ 1 - \exp\left(-\frac{hc\tilde{\nu}_{if}}{kT}\right) \right], \quad (3)$$

where  $k$  is the Boltzmann constant,  $T$  the absolute temperature and  $g_{ns}$  is the nuclear spin statistical weight factor.  $Q$ , the partition function, is given by

$$Q = \sum_i g_i \exp\left(-\frac{E_i}{kT}\right), \quad (4)$$

where  $g_i$  is the degeneracy of a particular state  $i$  with energy  $E_i$ . For  $\text{PH}_3$ ,  $g_i$  is  $g_{ns}(2J_i + 1)$  with  $g_{ns} = 8$  for all  $A_1$ ,  $A_2$  and  $E$  symmetries.

Previous work has looked in depth at the temperature-dependent partition function of phosphine (Sousa-Silva et al. 2014). This work produced accurate and fully converged values for the partition function for temperatures below 3000 K by the explicit summation of theoretical rotation–vibration energy levels of the molecule. The convergence dependence on temperature arises due to the growing contribution higher states make towards the value of the partition function as temperature increases. To achieve this convergence, 5.6 million energy levels with high accuracy were used, combined with

**Figure 3.** Ratio of effective partition function used in SAIITY,  $Q_{8000}$ , to the converged value,  $Q_{\text{total}}$ , calculated in Sousa-Silva et al. (2014). This ratio gives a measure of completeness of SAIITY as a function of temperature.

**Table 4.** Maximum temperatures for which the SAIITY line list is percentually complete.

$T_{\max}$ (K)	Completeness per cent
1014	100
1146	99
1797	80
1500	91
2000	70
2500	50

an additional 145 million calculated with an accurate vibrational component but with the rotational contribution estimated by a rigid rotor approximation, and consequently with a much decreased level of accuracy. However, the rotational states are anchored to the vibrational states, so an accurate vibrational description means that the energy level clusters remain valid (Yurchenko et al. 2005b), even if the degradation of accuracy from the rotational component makes the energies within the cluster only approximate. Consequently, their collective contribution to the partition function and related properties remains correct.

The  $T_{\max}$  for which molecular data is complete to a satisfactory degree can be found by computing the temperature-dependent partition function using only the energy levels under the lower energy threshold considered in the line list (here 8000  $\text{cm}^{-1}$ ), and then comparing its value to that of the complete partition function. By considering the ratio  $Q_{\text{limit}}/Q_{\text{total}}$ , where  $Q_{\text{total}}$  is the converged partition function value calculated by explicitly summing over all energy levels and  $Q_{\text{limit}}$  is the partition function calculated using only those levels with energies up to SAIITY’s threshold of 8000  $\text{cm}^{-1}$ . Fig. 3 shows SAIITY’s completeness with increasing temperature. As can be seen from the Table 4, SAIITY is over 90 per cent complete for temperatures below 1500 K, but quickly becomes depleted at higher temperatures. It is possible to use SAIITY to model temperatures over 1500 K by using the percentual loss of completeness to estimate the proportion of opacity missing from a spectrum (Neale, Miller & Tennyson 1996), but it is recommended that 1500 K is taken as a soft limit to the applicability of the SAIITY line list.

**Figure 4.** Overview of the full SAITY spectrum of  $\text{PH}_3$  for  $T = 300, 500, 1000$  and  $1500$  K, absorption cross-sections ( $\text{cm}^2/\text{molecule}$ ) with half width half maximum (HWHM) =  $0.5 \text{ cm}^{-1}$ . Looking at the minimum of the spectra, the cross-sections are ordered in increasing temperature.

Using the equations above and the present line list, multiple cross-sections were simulated for  $\text{PH}_3$ . Figs 4 and 5 illustrate the temperature dependence of phosphine for  $T = 300, 500, 1000, 1500$  and  $2000$  K. It can be seen that the spectra at higher temperatures have less features and a loss of sharp  $Q$ -branches. Fig. 5(c), covers the wavelength region  $3.8\text{--}5.1 \mu\text{m}$  which, as mention above, is of particular importance for the spectral characterization of brown dwarfs and gas giants.

Fig. 6 demonstrates how the density of lines per an absorption intensity  $I_{ij} = A \times 10^x$  unit changes with temperature, covering the whole wavenumber range  $0\text{--}10\,000 \text{ cm}^{-1}$ . As the temperature rises, the number of intense lines increases but the range of intensities in the spectrum becomes narrower. The Gaussian-like intensity distributions peak at  $I = 10^{-41}, 10^{-35}, 10^{-31}$  and  $10^{-31}$  for  $T = 298, 500, 1000$  and  $1500$  K, respectively. This is different from the intensity distribution found for  $\text{CH}_4$  by Yurchenko & Tennyson (2014), where the proportion of strong lines was found to be much larger.

**Figure 5.** SAITY absorption spectra of  $\text{PH}_3$  for  $T = 300, 500, 1000, 1500$  and  $2000$  K, convoluted with a Gaussian profile, HWHM =  $2 \text{ cm}^{-1}$ , for the 30(panel a), 10(panel b), 5(panel c) and 3(panel d)  $\mu\text{m}$  regions.

**Figure 6.** Number of intense lines as a function of intensity for different temperatures. The  $x$ -axis gives the log of the intensity in  $\text{cm}/\text{molecule}$ , while the  $y$ -axis represents the number of transitions per each  $10^x \text{ cm}/\text{molecule}$  bin.

#### 4.1 Comparison with experiment

Sousa-Silva et al. (2013) offer a detailed comparison of SYT to the existing experimental data, where it was found that it replicates very well the observed phosphine spectra at room temperature, with a maximum rms deviation from CDMS (Müller et al. 2005; Müller 2013) of  $0.076 \text{ cm}^{-1}$  for the rotational spectrum and of  $0.23 \text{ cm}^{-1}$  from HITRAN (Rothman et al. 2013). As can be seen from Fig. 8, the SAITY line list is also in excellent agreement with HITRAN (and incorporated CDMS data), and it is expected that SAITY will have slightly lower rms deviations from experiment at this temperature.

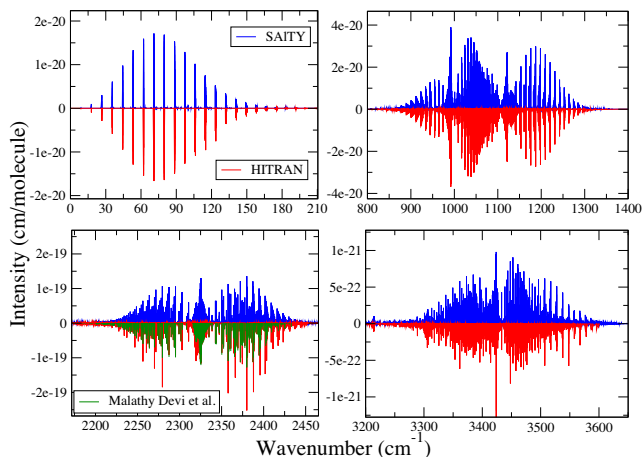

The most recent CDMS update (Müller 2013) contains a very comprehensive description of the pure rotational band of phosphine. Fig. 7 demonstrates that SAITY is in excellent agreement with the CDMS data. The transitions in the bottom-left box shows a deviation of approximately  $0.01 \text{ cm}^{-1}$ , while the rightmost box, at higher wavenumbers, shows a deviation of approximately  $0.04 \text{ cm}^{-1}$ .

The apparent intensity disagreements with HITRAN occur because of an overestimation of the intensity of some of the degenerate  $A_1 \leftrightarrow A_2$  transitions which are in such close proximity that they have been perceived as one doubly strong transition in the experimental

**Figure 7.** Comparison of the SAITY line list with the most recent phosphine data from CDMS at room temperature (Müller 2013).

**Figure 8.** Comparison of the SAITY line list with the phosphine data from HITRAN (Rothman et al. 2013) at room temperature; also shown are the recent results of Malathy Devi et al. (2014).

data. This has been partially resolved by Malathy Devi et al. (2014), who corrected these intensities for the region 1950 to 2450  $\text{cm}^{-1}$ . The bottom-left box in Fig. 8 includes this data, and it can be seen that SAITY is in much better agreement with it than with the HITRAN data. We recommend that the Malathy Devi et al. (2014) data should be included in the next release of HITRAN.

The data in HITRAN are generally very accurate for room temperature simulations. However, if the current HITRAN data base is used to simulate high-temperature spectra, the differences become much more striking, as can be seen in Fig. 9.

The only available data above 300 K comes from the Pacific Northwest National Laboratory (PNNL) who provide cross-sections for  $\text{PH}_3$  up to temperatures of 323 K (Sharpe et al. 2004). Comparisons with SAITY for  $T = 50^\circ\text{C}$ , or 323 K, can be seen in Fig. 10. The PNNL data is approximately 8 per cent weaker than SAITY's, but both are otherwise in good agreement. Given its larger density and coverage, it is recommended that SAITY is used to simulate cross-sections, even at low temperatures.

**Figure 9.** Comparison of the SAITY line list with the phosphine data from HITRAN (Rothman et al. 2013) at 1500 K.

**Figure 10.** Comparison of the SAITY absorption cross-sections for  $\text{PH}_3$  with PNNL and HITRAN at  $T = 50^\circ\text{C}$ ,  $\text{HWHM} = 0.076 \text{ cm}^{-1}$ .

## 5 CONCLUSIONS

An accurate and comprehensive line list for phosphine is presented, which has been called SAITY. It contains 16.8 billion transitions between 7.5 million energy levels and it is suitable for simulating spectra up to temperatures of 1500 K.

Its only limitations are: upper states with energies above 18 000  $\text{cm}^{-1}$  are excluded, and there is an effective short-end wavelength cut-off of 1  $\mu\text{m}$ , which is an unimportant region for  $\text{PH}_3$ . SAITY improves on the previous room temperature phosphine line list SYT in terms of the size of the basis set, corresponding refined PES and increased spectral range. It is therefore recommended that SAITY is used for all applications, even at low temperatures where SYT would provide reasonable results.

The tunnelling effect present in ammonia is predicted in phosphine but has yet to be observed in phosphine (Belov et al. 1981), due to its much higher inversion barrier (12 300  $\text{cm}^{-1}$ ). This tunnelling effect is not considered here, but rough preliminary calculations have predicted the position, size and intensity of transitions from split energy levels. Further work on this effect will be published elsewhere.

The SAITY line list is presented as the latest in a series of molecules as part of the ExoMol project, which aims to provide comprehensive line lists for every molecule relevant to the characterization of the atmospheres of cool stars and exoplanets. SAITY is freely available online in full or filtered by wavelength and intensity, from the ExoMol website. The line list in its entirety is very large but can be made more manageable by using cross-sections (Hill et al. 2013, available at ExoMol) or  $k$ -coefficients (Irwin et al. 1996).

## ACKNOWLEDGEMENTS

This work was supported by the ERC Advanced Investigator Project 267219. The research made use of the DiRAC@Darwin, DiRAC@COSMOS and the EMERALD HPC clusters. DiRAC is the UK HPC facility for particle physics, astrophysics and cosmology and is supported by STFC and BIS. The COSMOS Shared Memory system at DAMTP, University of Cambridge operated on behalf of the STFC DiRAC HPC Facility. This equipment is funded by BIS National E-infrastructure capital grant ST/J005673/1

and STFC grants ST/H008586/1, ST/K00333X/1. The EMERALD High Performance Computing facility is provided via the Centre for Innovation (Cfi). The Cfi is formed from the Universities of Bristol, Oxford, Southampton and UCL in partnership with STFC Rutherford Appleton Laboratory. We thank James Briggs (COSMOS) and Cheng Liao (SGI) for their help with the PLASMA eigensolver.

The authors would also like to thank Duncan A. Little, Hannah Lees, Sally Hewett, Helen Parks, Antonio Silva, Antonio S. Silva and Peter J. Day for their support and contribution.
