### In Brief

Damaged mitochondria are thought to accumulate if mitophagy is impaired and to cause Parkinson’s disease by continuously generating high levels of toxic reactive oxygen species (ROS). Pryde et al. show instead that proteolytic quality control ensues in these organelles to confine and diminish ROS by degrading the ROS-producing domain of complex I.

### Highlights

- Complex I is selectively vulnerable to proteolysis in depolarized mitochondria
- Complex I degradation extinguishes high ROS if mitophagy fails
- LON and ClpP bind and degrade complex I after mitochondrial stress induction
- Complex I abundance is coupled to mitochondrial homeostasis

# A LON-ClpP Proteolytic Axis Degrades Complex I to Extinguish ROS Production in Depolarized Mitochondria

## SUMMARY

Mitochondrial dysfunction is implicated in numerous neurodegenerative disorders and in Parkinson's disease (PD) in particular. PINK1 and Parkin gene mutations are causes of autosomal recessive PD, and these respective proteins function cooperatively to degrade depolarized mitochondria (mitophagy). It is widely assumed that impaired mitophagy causes PD, as toxic reactive oxygen species (ROS)-producing mitochondria accumulate and progressively drive neurodegeneration. Instead, we report that a LON-ClpP proteolytic quality control axis extinguishes ROS in depolarized mitochondria by degrading the complex I ROS-generating domain. Complex I deficiency has also been identified in PD brain, and our study provides a compelling non-genetic mechanistic rationale to explain this observation: intact complex I depletes if mitochondrial bioenergetic capacity is robustly attenuated.

## INTRODUCTION

Parkinson's disease (PD) is the second most prevalent neurodegenerative disorder (Schapira, 2008). Mitochondrial dysfunction is implicated in most PD genetic variants and is also reported in sporadic PD, suggesting mitochondrial homeostasis and PD are connected (Schapira, 2008). For instance, brains from sporadic PD patients typically display a selective deficiency in mitochondrial complex I activity (via an uncertain mechanism), and they comprise mitochondrial/cellular oxidative damage (Schapira et al., 1989; Keeney et al., 2006; Parker et al., 2008). Mutations in PINK1 (a mitochondrial kinase) and Parkin (a cytosolic E3 ubiquitin ligase) are two autosomal recessive causes of PD (Kitada et al., 1998; Valente et al., 2004). PINK1-Parkin function cooperatively to degrade damaged/depolarized mitochondria via autophagy (mitophagy) (Narendra et al., 2010). PINK1 is the damage sensor; it is imported into the inner mitochondrial membrane (IMM) of polarized mitochondria and degraded. Mitochondrial depolarization terminates IMM import (Malhotra et al., 2013), so PINK1 rapidly accumulates in the outer mitochondrial mem-

brane (OMM) and phospho-activates Parkin (Kane et al., 2014) to initiate mitophagy.

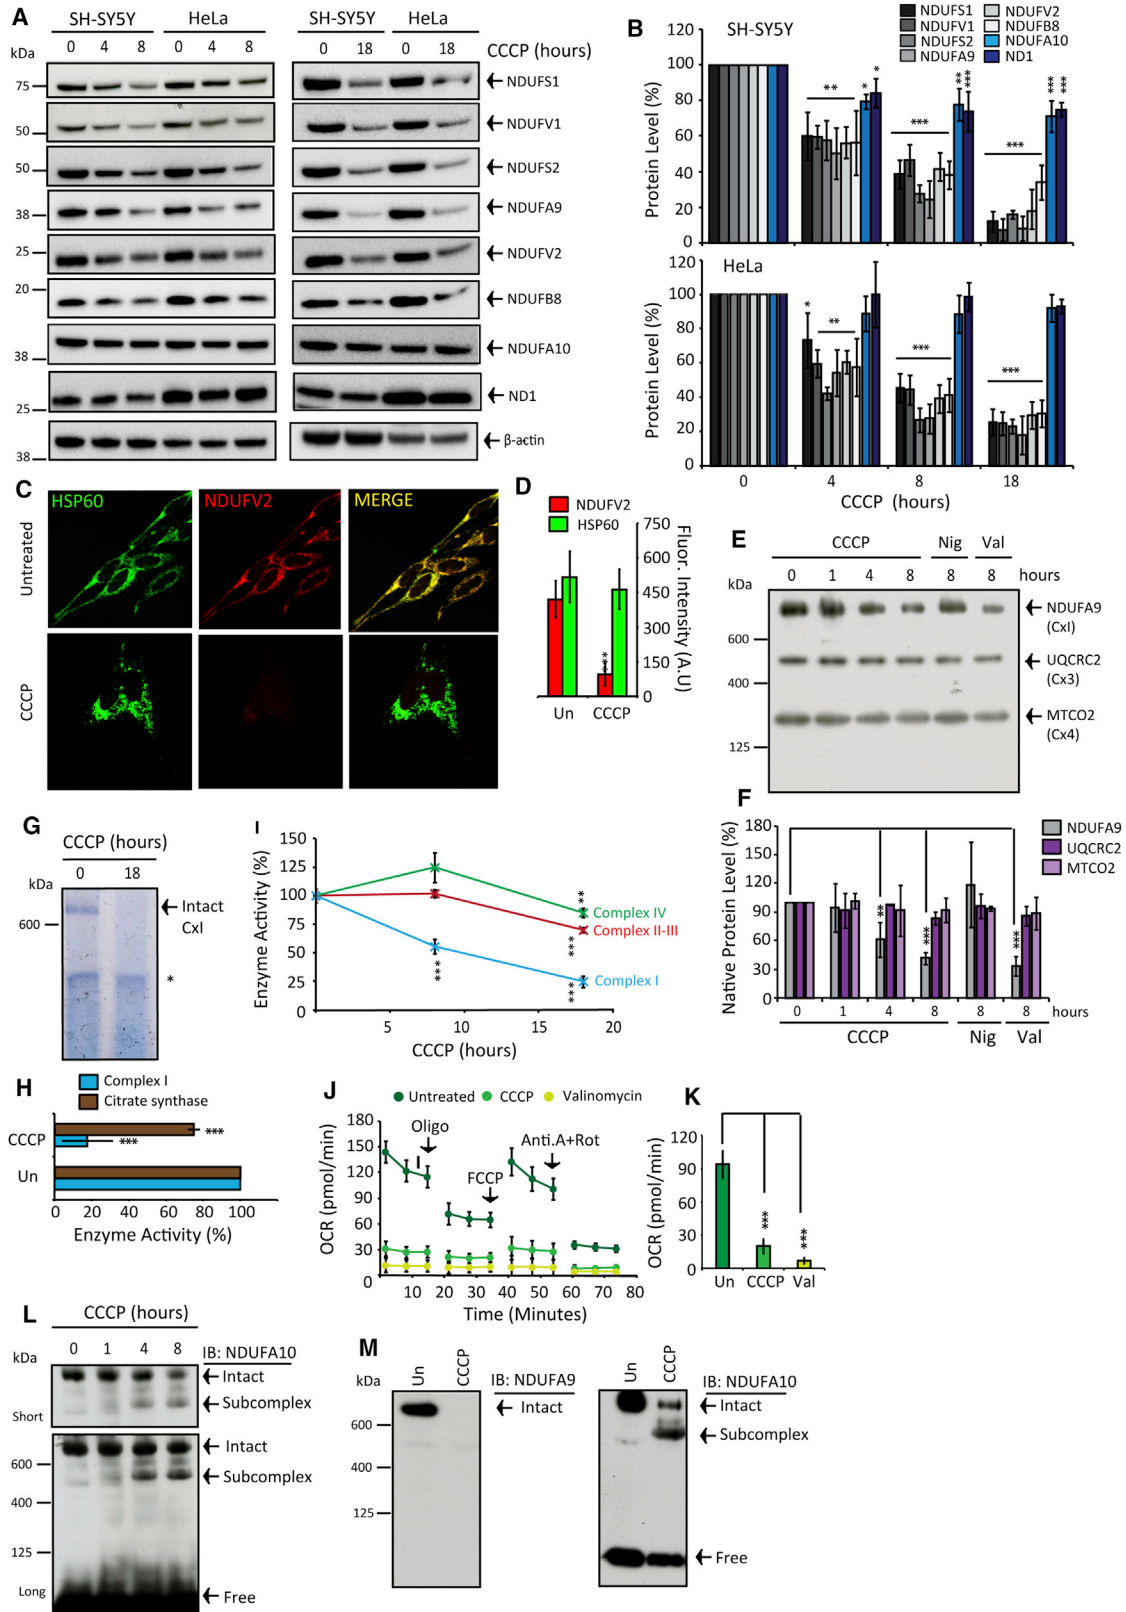

Mitochondria also can produce copious amounts of deleterious reactive oxygen species (ROS). Respiratory complex I has long been considered the predominant source, and complex I abundance parallels mitochondrial ROS-generating capacity (Lambert et al., 2010; Miwa et al., 2014). Oxygen is reduced to ROS via a side reaction with the NADH-reduced flavin cofactor (Pryde and Hirst, 2011). In isolated mitochondria, the rates of ROS formation accelerate significantly when inhibitors, mimicking molecular damage, impair respiration (Kushnareva et al., 2002). It is assumed that high ROS-generating damaged mitochondria accumulate if mitophagy fails and these organelles contribute to, or cause, PD via ongoing oxidative damage to affected neurons. Yet other than inference, the empirical basis supporting this orthodoxy is lacking. Little is known about the fate and properties of the organelles normally cleared by mitophagy; their fundamental ROS-generating capacities are not established or defined. It is also feasible that mitophagy-independent PINK1 and Parkin activities cause PD (Chung et al., 2001; Morais et al., 2014). Elucidating why PINK1-Parkin deficiency causes PD remains the outstanding question in the field.

Here we report that damaged mitochondria do not perpetually generate high ROS, as an intra-mitochondrial LON-ClpP proteolytic quality control axis functions to extinguish ROS in these organelles by degrading the ROS-producing domain of complex I.

## RESULTS

### Mitochondrial Complex I Is Selectively Degraded in Depolarized Mitochondria

To determine the fate of complex I in damaged organelles, we induced mitophagy using canonical methodology (Narendra et al., 2010), and we chemically depolarized mitochondria with the protonophore CCCP in SH-SY5Y and HeLa cells. Both cell types express PINK1 but HeLa cells do not express Parkin (Figures S1A and S1B). Mammalian complex I comprises 44 discrete subunits (Zhu et al., 2016). The peripheral arm protrudes into the matrix and catalyzes NADH oxidation, ROS production, and ubiquinone reduction. The membrane arm resides in the IMM and mediates proton translocation. Recently, high-resolution structures revealed the arrangement of all constituent subunits and redox/catalytic centers (Figure S1C) (Zhu et al., 2016).

(legend on next page)

In both cell types, CCCP progressively diminished both catalytically core and accessory peripheral arm FV1, FV2, FS1, FS2, and FA9 subunits (core subunits depicted in Figure S1D); all decreased by ~35%–40%, 60%–70%, and 80%–95% following 4-, 8-, and 18-hr CCCP, respectively (Figures 1A and 1B). In contrast, two subunits residing in the membrane arm, FA10 and ND1, were maintained. However FB8 notably depleted, thus not all membrane arm subunits were preserved. Peripheral arm depletion exceeded the magnitude of loss ascribable to mitophagy. In SH-SY5Y cells, a cohort of matrix and IMM proteins (as well as ND1 and FA10) maximally reduced by 20%–30%; these were largely unaffected in HeLa cells (Figures S1E–S1G). A notable exception was the complex III subunit UQCRC2, which decreased by 60%–70% in SH-SY5Y cells only. Figures 1C and 1D show FV2 immunostaining (core subunit), but not HSP60, greatly diminished in CCCP-treated HeLa cells. Therefore, enduring depolarized mitochondria are devoid of the catalytically active peripheral arm.

Native-PAGE immunoblot analysis revealed that subunit depletion corresponds to intact complex I degradation (Figures 1E, 1F, and 1M; Figures S1H and S1I), and both flavin and Q-site activities robustly diminished (Figures 1G–1I). Neither the amount nor size of complexes III and IV were affected during depolarization (Figures 1E and 1F; Figures S1H and S1I), and, after 18 hr, complex II–IV activities decreased by only ~25% (Figure 1I). As expected, diminished complex I robustly impaired oxygen consumption rates (Figures 1J and 1K).

Degradative subcomplex intermediates were not observed when immunoblotting for peripheral arm subunits, but a large complex emerged when probing for FA10 (Figures 1L and 1M) and the molecular weight shift was commensurate with membrane arm. Subcomplex abundance increased inversely to declining intact complex I levels (Figures 1L and 1M). Desynchronized peripheral and membrane arm degradation is perhaps not surprising considering distinctive modules assemble into the final configuration (Koopman et al., 2010). Finally, we confirmed that PINK1 is not requisite for CCCP-induced peripheral arm turnover (Figures S1J–S1O). Taken together, the peripheral arm is selectively vulnerable to proteolysis after depolarization independently of PINK1/Parkin/bulk mitophagy.

### **m $\Delta\psi$ Dissipation Signals Peripheral Arm Degradation**

What drives complex I degradation following mitochondrial depolarization? CCCP equilibrates protons across the IMM, thereby dissipating the membrane potential (m $\Delta\psi$ ) and pH difference (m $\Delta$ pH) components of the proton-motive force ( $\Delta$ p), as well as terminating  $\Delta$ p-driven ATP synthesis and m $\Delta\psi$ -driven

protein import. We used nigericin (Nig; dissipates m $\Delta$ pH, increases m $\Delta\psi$ ), valinomycin (Val; dissipates m $\Delta\psi$ , increases m $\Delta$ pH), oligomycin (Oligo; inhibits ATP synthase), and cycloheximide (CHX; inhibits cytosolic translation) to dissect how CCCP signals proteolysis.

CHX did not significantly alter steady-state complex I levels (Figures 2A and 2B; Figures S3A and S3B), but it greatly diminished short-lived TIM23 (Figures S3A and S3B). Therefore, peripheral arm turnover is a stimulated response to depolarization and not attributable to half-life kinetics. Figures S2A and S2B show only CCCP and Val quenched TMRM<sup>+</sup> (a m $\Delta\psi$  reporter) and induced peripheral arm loss (Figures 1E, 1F, and 2A–2D).

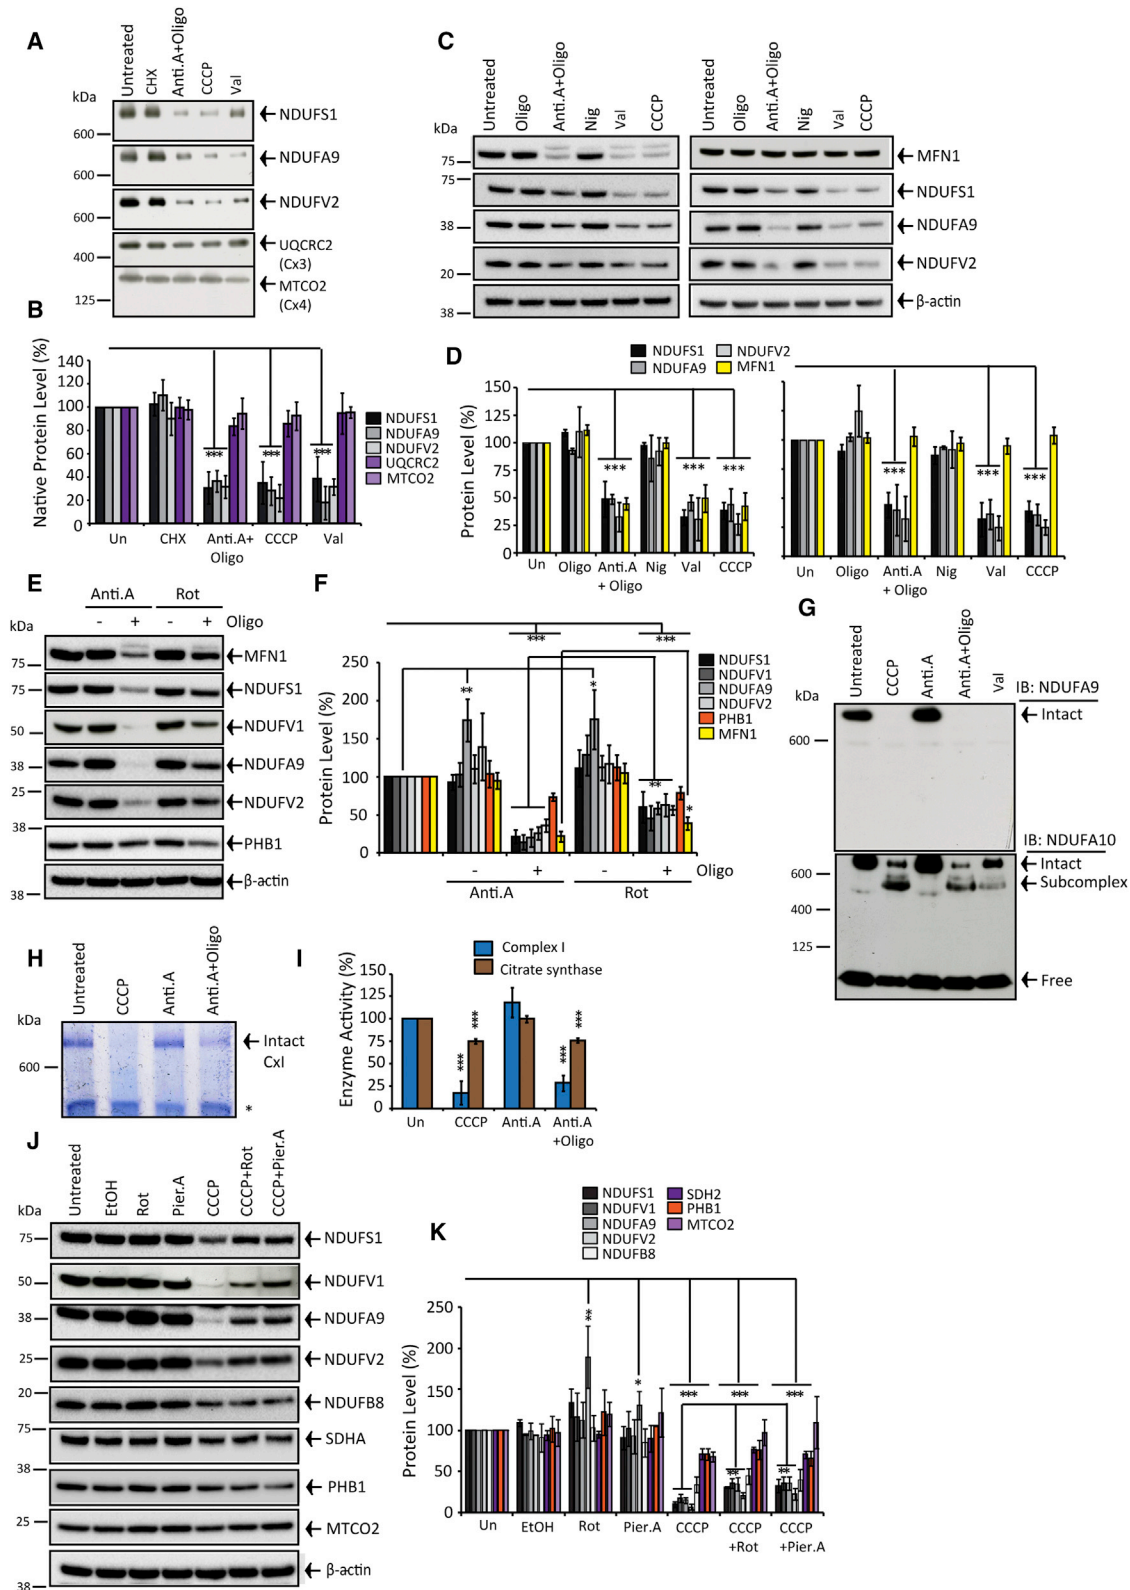

Blocking respiration with the complex III inhibitor antimycin A (Anti.A) only depleted complex I (Figures 2C–2G) and in-gel activity (Figures 2H and 2I) when combined with Oligo. Anti.A + Oligo quenched TMRM<sup>+</sup> similarly to CCCP (Figure S2B), whereas Anti.A alone partially lowered TMRM<sup>+</sup> (Figure S2B), i.e., sufficient m $\Delta\psi$  is maintained via ATP hydrolysis by ATP synthase to preserve complex I. The complex I Q-site inhibitor rotenone (Rot) essentially recapitulated the Anti.A effect (Figures 2E and 2F). However, we noted that the degradation efficacy of Rot + Oligo was approximately two times weaker compared to Anti.A + Oligo. To establish if Rot somehow impairs proteolysis, we included Rot alongside CCCP and found ~2-fold less peripheral arm depletion (Figures 2J and 2K; Figure S3C). Similar results were observed with an alternative Q-site inhibitor, piericidin A (Figures 2J and 2K; Figure S3C).

### **Activating Mitophagy Triggers Mitochondrial Oxidative Stress and Peripheral Arm Depletion**

Next, we sought to determine if activating mitophagy elevates mitochondrial ROS production and to explore how complex I degradation affects ROS. Mitochondrial aconitase (mt-acnitase) activity is an established reporter of intra-mitochondrial ROS (Gardner et al., 1995). Here, aconitase activity reduced by 50%–60% during 15- to 30-min Anti.A  $\pm$  Oligo treatment (Figures 3A and 3B). Cells express two aconitase isoforms compartmentalized in the matrix and cytosol (Gardner et al., 1995). We isolated mitochondria from cells at  $\pm$ 1-hr Anti.A treatment and found eradicated aconitase activity; thus, 55% of the total rate is attributable to mt-acnitase. Rot  $\pm$  Oligo abolished mt-acnitase activity after ~1-hr treatment, and CCCP progressively inactivated mt-acnitase albeit at a slower rate (Figure 3A). Including the antioxidant NAC diminished CCCP degradative potency, suggesting ROS contributes to the orchestration of peripheral arm turnover (Figure 3C). Thereby, conditions that deplete the peripheral arm robustly augment mitochondrial ROS production.

(A and B) Native-PAGE. HeLa cells  $\pm$  8-hr cycloheximide (CHX), antimycin A + oligomycin (Anti.A + Oligo), CCCP, or valinomycin (Val) treatment (n = 3). (C and D) SH-SY5Y (left panel) and HeLa (right panel) cells  $\pm$  8-hr Oligo, Anti.A + Oligo, nigericin (Nig), Val, and CCCP (n = 3).

(legend continued on next page)

If oxidative stress initiates peripheral arm turnover, why does complex I maintain after 18-hr Anti.A or Rot treatment? We probed the precise kinetic relationship between Anti.A exposure and complex I stability. Remarkably, FS1, FV1, FA9, and FV2 levels declined by 20%–50% after 2- to 4-hr Anti.A, but subsequently they recovered to basal levels after 8 hr (Figures 3D and 3E); the recovery was blocked by CHX, and we observed concurrent upregulation of nuclear-encoded peripheral arm, but not membrane arm, transcript levels (Figures 3D–3F). The magnitude of transcript upregulation is consistent with previously determined mitochondria-nuclear retrograde signaling (Münch and Harper, 2016). Figures 2H and 2I confirm that intact complex I comprising reconstructed peripheral arm is catalytically active.

Is mitochondrial ROS production affected by complex I degradation? In live cells ROS measurements were limited to Anti.A treatments using mitoSOX (as equilibration of ROS reporters requires  $m\Delta_{\psi}$ ). Anti.A concurrently increased NAD(P)H auto-fluorescence, which decreases the complex I flavin reduction potential (Pryde and Hirst, 2011) (Figures 3G and 3H), and stimulated ROS formation by ~5- to 6-fold (Figures 3I and 3J). NAD(P)H intensity maintained during Anti.A treatment (Figures 3G and 3H), but ROS production lowered (Figures 3I and 3J) proportionally to peripheral arm depletion (Figures 3D and 3E). Furthermore, mitochondria fractionated from CCCP-treated cells generated significantly less NADH-induced ROS (Figure 3K). Mitochondrial ROS production progressively diminishes as complex I is degraded.

### LON and ClpP Bind and Degrade the Peripheral Arm

Matrix and IMM proteins are degraded by an elaborate network of proteases (Quirós et al., 2015), including m-AAA as well as stress-activated LON and ClpP. The proteasome (Radke et al., 2008) and lysosome (Soubannier et al., 2012) also can mediate degradation.

Proteasomal or lysosomal inhibition did not affect peripheral arm turnover (Figures 4A–4D). Silencing LON impaired depolarization-induced FS1 (1.7 $\times$ ), FV1 (1.9 $\times$ ), FA9 (1.4 $\times$ ), and FV2 (2.0 $\times$ ) degradation, whereas silencing ClpP retarded FV1 (1.7 $\times$ ) and FV2 (3.1 $\times$ ) turnover (Figures 4E and 4F; Figures S3F and S3G), suggesting subunit-dependent proteolytic redundancy and exclusivity. Remnant turnover may reflect residual LON/ClpP activities or less efficient turnover pathways, and redundancy is a hallmark of the proteolytic network (Quirós et al., 2015). Silencing LON impaired mt-aconitase degradation in depolarized mitochondria (Figures S3D and S3E).

Do degradative proteases dock to intact complex I as part of the degradative cascade? We immuno-captured intact complex I via FB6; Figure 4G confirms co-precipitation with distal FV2 and FS1 subunits. LON and ClpP significantly enriched with precipitated intact complex I after 4-hr Anti.A treatment (Figure 4G).

Reverse capture of LON also precipitated several of the degradable peripheral arm subunits (Figure 4H) (ClpP not unsuccessfully precipitated). Finally, Figure 2J revealed that rotenone impaired peripheral arm turnover, and Figure 4G shows rotenone diminished Anti.A-induced complex I and LON precipitation, suggesting Q-site-inhibited complex I is more resistant to proteolysis and protease binding.

## DISCUSSION

Molecular mechanisms of PINK1-Parkin mitophagy have been studied intensely; however, the cause of PD is not understood. Here, we show that the widespread assumption that accumulating impaired mitochondria perpetually generate high toxic ROS levels requires reconsideration; quality control ensues to extinguish ROS by degrading complex I and, thus, constraining the putative toxicity phase (cartoon depiction in Figure 4I). Challenging studies are required to establish if the limited phase of high ROS is sufficient to cause PD and to determine if accelerating complex I degradation can be harnessed therapeutically.

We also provide evidence for an intriguing stress-induced complex I degradation-retrograde signaling-protein synthesis/import-repair cascade. Elucidating the orchestration of retrograde signaling and how repair is coordinated require further investigation, but presumably they enable respiration renewal by clearing/repairing damage-prone peripheral arm if the organelles retain some  $m\Delta_{\psi}$ . ATP hydrolysis by ATP synthase generates  $m\Delta_{\psi}$  when the respiratory chain is impaired; thus, if glycolytic capacity is low (e.g., neurons [Almeida et al., 2001]), the repair pathway will fail, which might explain complex I deficiency in PD brains; thus far only mtDNA mutations had been considered (Kraytsberg et al., 2006). Intriguingly, in both PD human brains and PD models, as well as generic ROS-inducing conditions, peripheral arm subunits are selectively oxidized (including FS1, FS2, FV1, and FS6) (Keeney et al., 2006; Chinta et al., 2007; Danielson et al., 2011; Chouchani et al., 2013; Gorenkova et al., 2013). The LON-ClpP degradative axis now provides a plausible mechanistic foundation to bridge deficiency with oxidative damage.

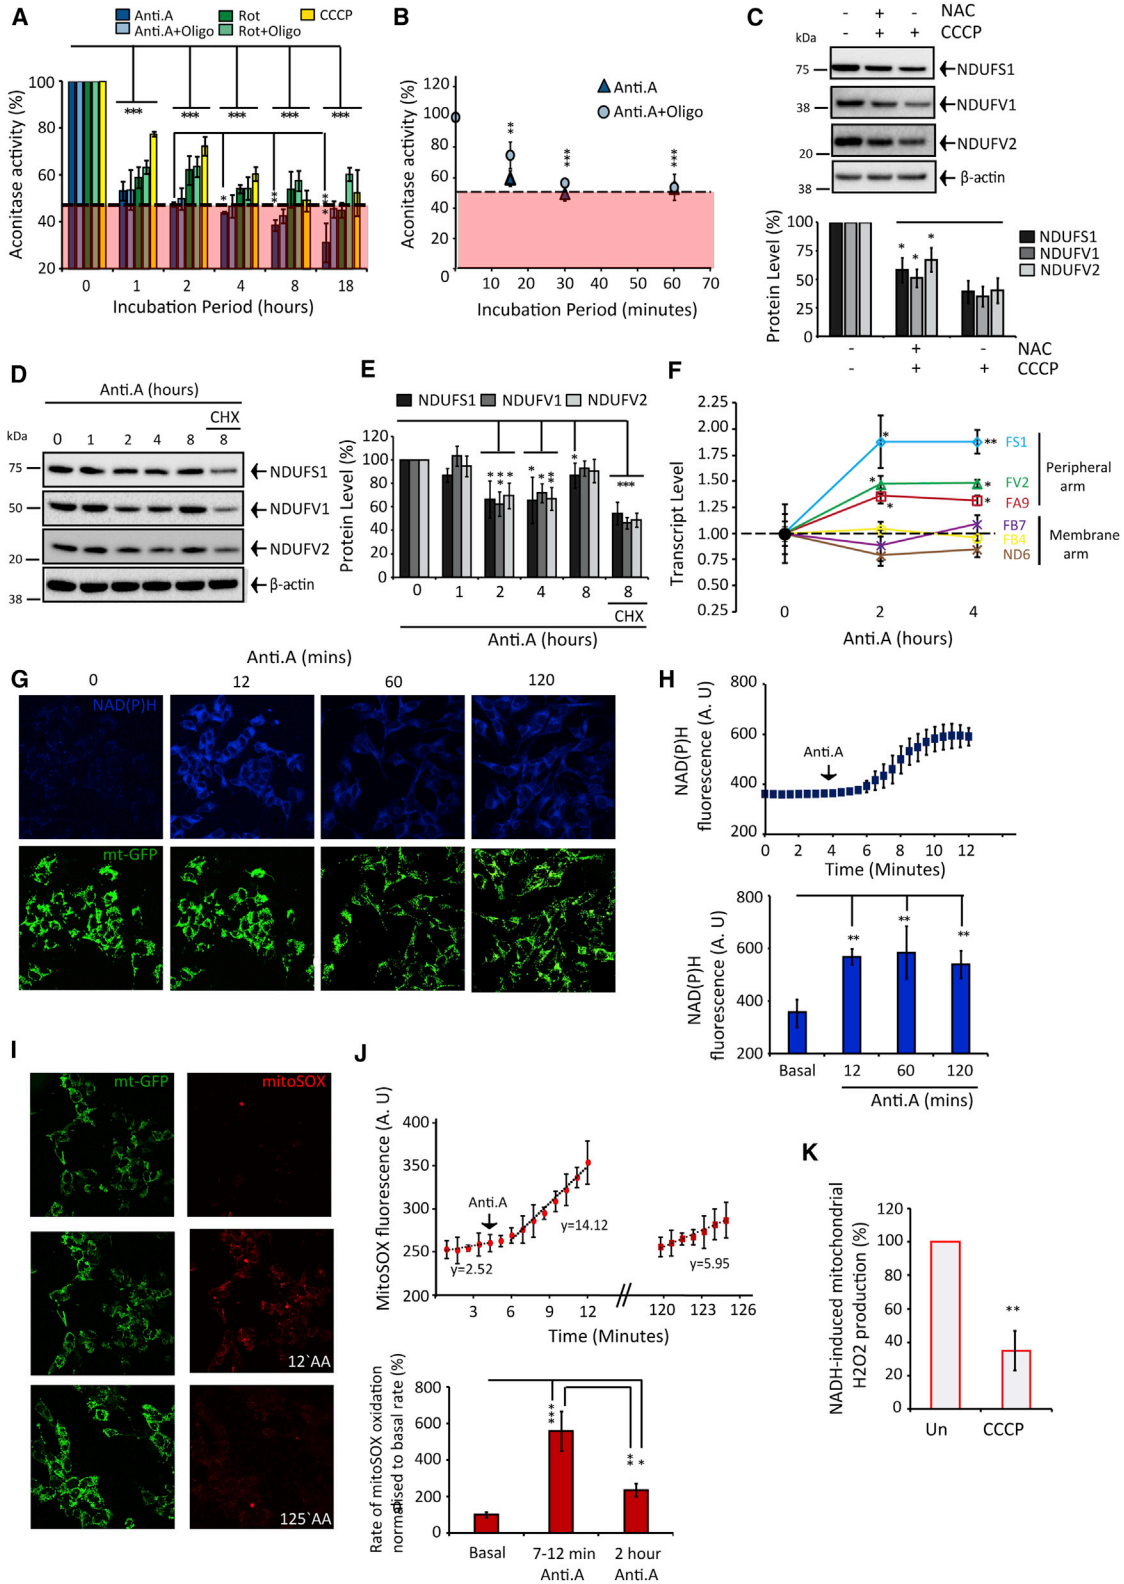

Comprehensive in vitro experimentation is required to unravel the degradative mechanism. Elucidating degrons and inter-subunit degradative dependencies for all constituent peripheral arm subunits is experimentally daunting, considering single-point mutations can destabilize intact complex I (Varghese et al., 2015). Robust investigation will require structural determination of degradative intermediates combined with carefully executed mutagenesis. Previous studies revealed LON comprises specificity for both oxidized peptide and Fe-S clusters (Bota and Davies, 2002; Ngo and Davies, 2009; Bender et al., 2011; Kim et al., 2015). Thereby, complex I Fe-S clusters could form ROS sensors, with their susceptibility to oxidation signaling degradation

(legend on next page)

in combination with oxidized polypeptide or hydrophobic patches in denatured regions (Nishii et al., 2005; Ondrovicová et al., 2005).

The finding that Q-site-inhibited complex I is less vulnerable to turnover provides a mechanistic foundation for subsequent studies and indicates that the Q-site apparatus systemically controls the propensity of peripheral arm degron formation. Inactive complex I reverts to a distinctive deactive state (Zhu et al., 2016) *in vitro* (Kotlyar and Vinogradov, 1990) and *in vivo* (Maklashina et al., 2002). Deactive conformational change is largely restricted to Q-site architecture, exposing thiols in ND1, ND3, and FA9 (Galkin et al., 2008; Babot et al., 2014) to oxidation/redox modification (Gorenkova et al., 2013). Rotenone retards the deactive transition (Grivennikova et al., 1997) by probably binding peptide, which drives the conversion so complex I is jammed into a non-deactivate conformation. Accordingly, the deactive enzyme may form the degradative ground state by revealing degrons/exposing oxidizable peptide, which enables subsequent denaturation and damage contagion in a feedforward-like proteolytic mechanism. Considering rotenone- and MPP- (another Q-site inhibitor) treated mice exhibit parkinsonism, a convolution of defective respiration and suppression of complex I degradation may contribute.

In conclusion, our study establishes a fundamental connectivity between mitochondrial homeostasis and complex I. Previously, complex I deficiency in diseases such as PD has been considered in the context of genetic defects in constituent subunits and assembly factors. We now show complex I stability is governed by an additional non-genetic regulatory dimension. We provide a conceptual framework that couples complex I activity/abundance with perturbed cellular homeostasis. For instance, disease-associated pathways that trigger systemic or local depolarization of the mitochondrial pool, such as augmented nitric oxide during endoplasmic reticulum (ER) dysfunction or excitotoxicity, should induce peripheral arm depletion.

## EXPERIMENTAL PROCEDURES

### Cell Culture

HeLa (S3) and fibroblasts were cultured in DMEM Glutamax (Life Technologies) and SH-SY5Y cells in DMEM/F12 (Life Technologies) supplemented with 10% fetal bovine serum (FBS, Life Technologies), 1 mM pyruvate (Life Technologies), non-essential amino acids (Life Technologies), and penicillin/streptomycin. Cells were cultured in a 37°C, 5% CO<sub>2</sub> humidified atmosphere.

### SDS-PAGE and Immunoblots

1% Triton X-100 extracts (supplemented with 1× EDTA-free protease/phosphatase inhibitors, Pierce) were equally loaded (bicinchoninic acid [BCA] pro-

tein assay), DTT reduced, resolved using SDS-PAGE (pre-cast 4%–12% gels; Novex, Life Technologies), and transferred (wet transfer) onto polyvinylidene fluoride (PVDF) membranes (GE Healthcare, Amersham Hybond, 0.45 μm). Membranes were blocked and then incubated with primary antibody overnight (4°C), followed by 1:2,000 horseradish peroxidase (HRP)-conjugated secondary antibodies (Dako) for 1 hr. Enhanced chemiluminescence (ECL) Clarity chemiluminescent substrate (Bio-Rad) was used to detect immunoreactive proteins by the ChemiDoc MP (Bio-Rad) or X-ray film. Unless otherwise stated, all immunoblots are adjusted for β-actin level and normalized to untreated samples (100%).

### Blue Native-PAGE and in-Gel Complex I Activity Measurements

Cell pellets were solubilized in 50 μL 1 M 6-aminocaproic acid, 50 mM bistris (pH 7, HCl), and 1.5% n-Dodecyl β-D-Maltopyranoside supplemented with protease inhibitors. Clarified lysates were added to Serva blue G loading buffer and loaded onto non-commercial 3%–12% acrylamide gels (Schägger, 1995). Complexes were sufficiently resolved and membranes subsequently processed as standard.

For in-gel activity measurements, the cathode buffer was replaced after 12 min with 50 mM tricine and 15 mM bistris without Serva blue. After 65 min, the gels were stained with a 2 mM Tris (pH 7.4, HCl), 150 μM NADH, and 3 mM nitroblue tetrazolium for 1–2 hr at 37°C. The assay buffer was exchanged with 10% acetic acid-40% methanol followed by distilled water. Gels were scanned and intensity quantified using ImageJ software.

### Enzyme Kinetics and Respiration Measurements

For citrate synthase activity, the conversion of 5,5'-dithio-bis-[2-nitrobenzoic acid] (DTNB) to thionitrobenzoic acid (TNB) in clarified cell lysates was monitored at 412 nm. Seahorse Technology was used to measure respiration in HeLa cells ±8 hr prior to CCCP or valinomycin treatment. For aconitase activity, NADP<sup>+</sup> reduction during the conversion of citrate to α-ketoglutarate was monitored at 340 nm. Respiratory complexes I, II–III, and IV activities were determined by measuring rotenone-sensitive NADH:Q<sub>1</sub> oxidoreduction (340 nm), antimycin A-sensitive succinate:cytochrome c oxidoreduction (550 nm), and reduced cytochrome c oxidation (550 nm), respectively.

### Real-Time qPCR of mRNA

RNA was extracted from antimycin A-treated SH-SY5Y cells using the RNeasy kit (QIAGEN) and converted to cDNA by the QuantiTect reverse transcription kit (QIAGEN). The QuantiTect SYBR Green kit (QIAGEN) was used with QuantiTect Primer Assays (QIAGEN) to determine mRNA levels by real-time qPCR, and measurements were normalized using the transcript levels for β-actin. Experiments were carried out in triplicate, and each measurement also was performed in triplicate. Relative expression was calculated using the ΔC<sub>T</sub> method.

### Immunofluorescence

HeLa cells were seeded at 3 × 10<sup>5</sup> on 24-mm glass coverslips in six-well plates and cultured overnight. Following requisite CCCP treatment, cells were fixed in 4% paraformaldehyde, PBS washed, and solubilized in PBS-0.25% Triton X-100 (20 min, room temperature [RT]). Blocking was performed overnight in PBS-5% BSA (4°C). Anti-HSP60 and anti-NDUFB2 (both 500× in blocking buffer) were co-incubated for 90 min (RT), followed by anti-rabbit Alexa Fluor 594- and anti-mouse Alexa Fluor 488-conjugated secondary antibodies (500× in PBS) for 60 min (RT).

## Figure 3. Activating Mitophagy Induces Mitochondrial Oxidative Stress and Triggers Peripheral Arm Degradation

(A and B) Aconitase activity in HeLa cells after antimycin A (Anti.A) ± oligomycin (Oligo), rotenone (Rot) ± Oligo. Red zone indicates activity attributable to the cytosolic isoform. (n = 4–5).

(C) HeLa cells ± 8-hr CCCP ± NAC (n = 3).

(D and E) Anti.A-treated SH-SY5Y cells ± cycloheximide (CHX) (n = 3).

(F) mRNA levels in SH-SY5Y cells ± Anti.A treatment (n = 3).

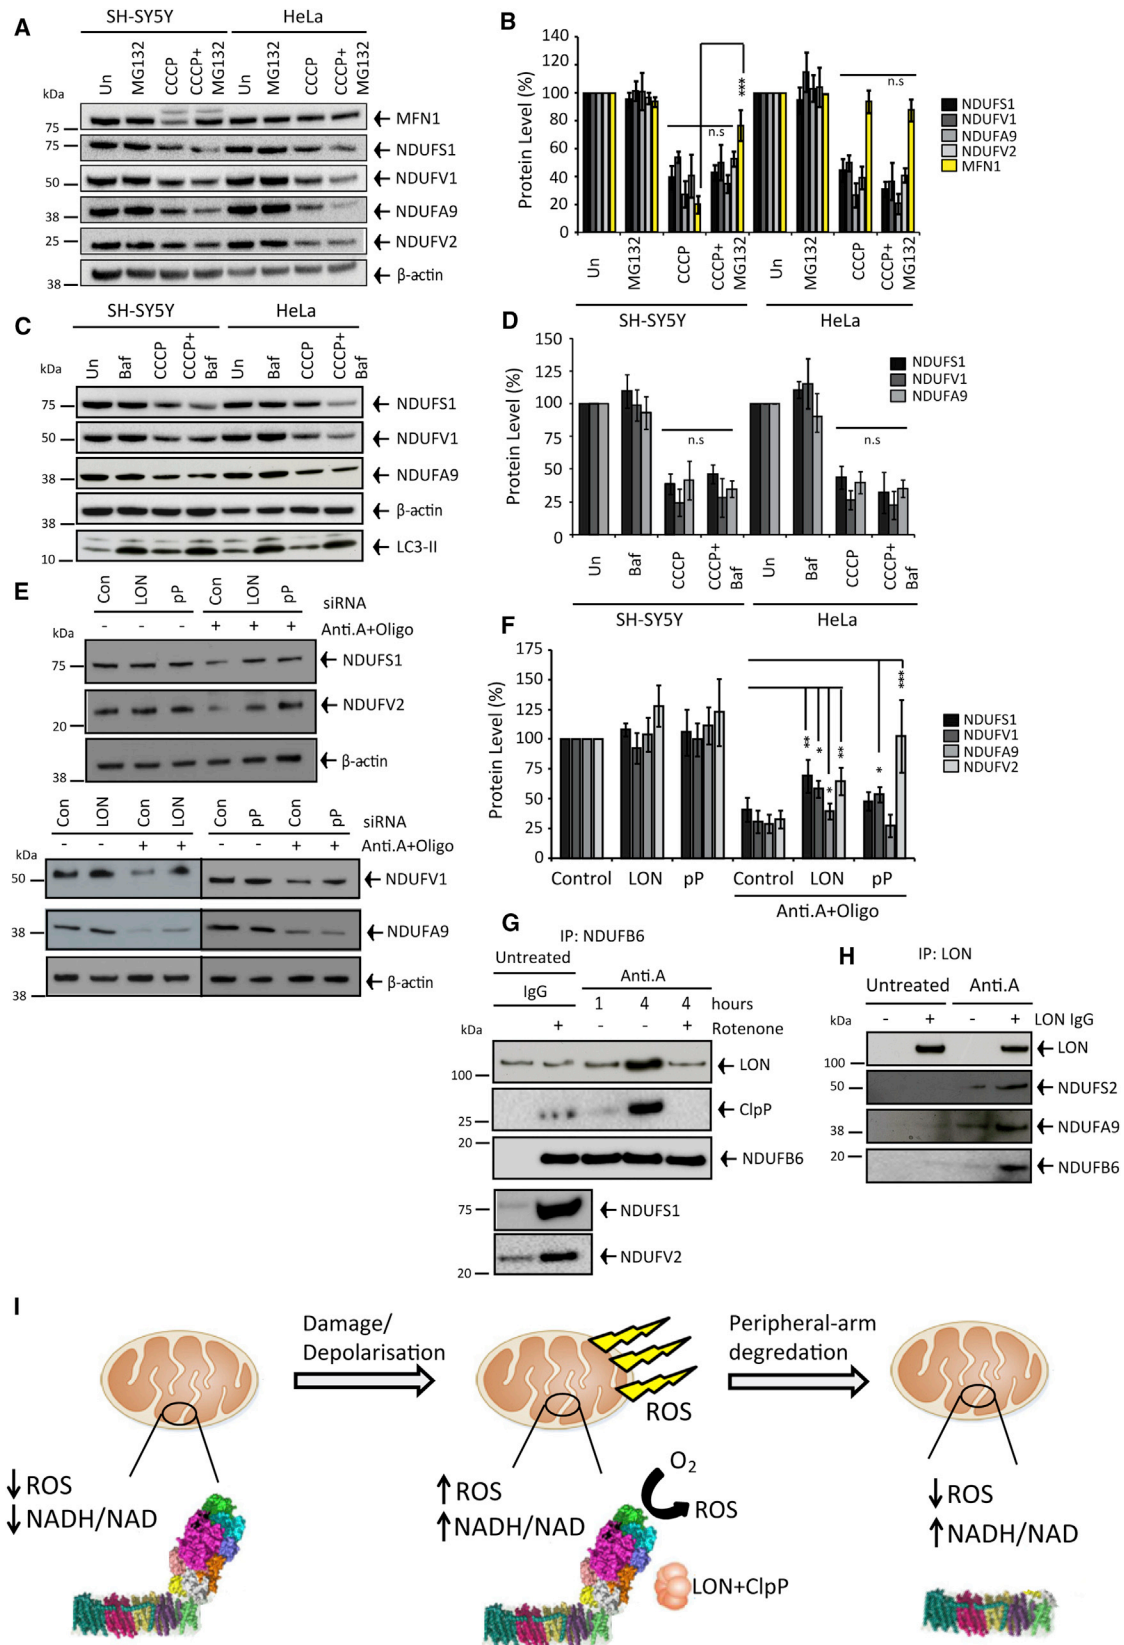

(G and H) NAD(P)H autofluorescence (a.u.) in mitochondrial-GFP (mt-GFP)-expressing SH-SY5Y cells during Anti.A treatment (n = 3).

(I and J) Rates (a.u.) of ROS in mt-GFP SH-SY5Y cells incubated with mitoSOX and treated with Anti.A (n = 3).

(K) NADH-induced H<sub>2</sub>O<sub>2</sub> production in mitochondria isolated from HeLa cells ± 8-hr CCCP (n = 3). All data in the figure are presented as mean + SDM.

See also Figure S2.

(legend on next page)

### Live-Cell Imaging

SH-SY5Y cells expressing mt-GFP or HeLa cells were seeded onto 22-mm glass coverslips in six-well plates for 48 hr ( $1 \times 10^5$ /well), and then they were loaded with 25 nM or 10 nM TMRM<sup>+</sup> (Thermo Fisher Scientific) (30 min in Hank's balanced salt solution (HBSS), RT). For ROS measurements, 20  $\mu$ M MitoSOX (HBSS) was added for 10 min prior to rate measurements. NAD(P)H autofluorescence was excited at 351 nm and measured between 375 and 470 nm.

### LON and ClpP Silencing

RNAi Max (Thermo Fisher Scientific) and Opti-MEM (Thermo Fisher Scientific) were used to silence  $2 \times 10^5$  HeLa cells (according to the manufacturer's instructions) with 5 nM small interfering RNA (siRNA) LON (Thermo Fisher Scientific stealth siRNAs; HSS113887 and HSS113888), 5 nM siRNA ClpP (Thermo Fisher Scientific stealth siRNAs; HSS112033 and HSS112034), or 5 nM control siRNA (Thermo Fisher Scientific stealth siRNAs negative control) in six-well plates for 48 hr prior to treatment.

### Complex I-LON and ClpP Co-immunoprecipitation

100  $\mu$ L (~800–1,000  $\mu$ g) of clarified PBS-1.5% n-Dodecyl  $\beta$ -D-Maltopyranoside lysates were incubated with recombinant protein G agarose (rPG agarose) (Life Technologies) for 45 min, subsequently sedimented, and supernatants were added to 30  $\mu$ L sedimented rPG prior coated with anti-NDUFB6 (200 $\times$ ) or anti-LON (200 $\times$ ) for 2 hr (4°C). Beads were washed three times (PBS, 4°C), and antibody-antigen conjugates were eluted in 0.1 M glycine (pH 2.5, Life Technologies) and neutralized by 1M Tris. DTT-reduced, 70°C-heated samples were resolved by SDS-PAGE and antigens were detected by immunoblot.

### Statistical Analysis

All data are expressed as the mean + SD of the mean (SDM). Statistical significance was calculated by using Student's t test, the nonparametric Kruskal-Wallis test (comparing more than two datasets), or the nonparametric Mann-Whitney test (comparing two datasets) on at least triplicate experiments (see figure legends). Considered significant,  $p < 0.05$  is denoted with a single asterisk whereas  $p < 0.01$  and  $p < 0.001$  are denoted with two and three asterisks, respectively.

### Figure 4. LON and ClpP Bind Intact Complex I and Mediate Peripheral Arm Degradation

(A–D) SH-SY5Y and HeLa cells  $\pm$  8-hr MG132 (n = 3) or bafilomycin (Baf) (n = 3)  $\pm$  CCCP.

(E and F) Control (n = 4), LON (n = 3), or ClpP (n = 3) silenced HeLa cells  $\pm$  8-hr antimycin A (Anti.A) + oligomycin (Oligo).

(G and H) NDUFB6 precipitation with ClpP (n = 3) and LON (n = 3) and LON precipitation with complex I (n = 3)  $\pm$  Anti.A  $\pm$  rotenone.

(I) Cartoon model of proteolytic quality control in depolarized mitochondria to extinguish ROS production. All data in the figure are presented as mean + SDM. See also Figure S3.
