Running Title: PET lung image quantification
Word Count: 6319
Keywords: Pulmonary, lung inflammation, molecular imaging, positron emission tomography
ABSTRACT

Millions of people are affected by respiratory diseases, leading to a significant health burden globally. Due to the current insufficient knowledge of the underlying mechanisms that lead to the development and progression of respiratory diseases, treatment options remain limited. To overcome this limitation and understand the associated molecular changes, non-invasive imaging techniques such as positron emission tomography (PET) and single photon emission computed tomography have been explored for biomarker development, with $^{18}$F-fluorodeoxyglucose ($^{18}$F-FDG) PET imaging being the most studied. The quantification of pulmonary molecular imaging data remains challenging due to variations in tissue, air, blood and water fractions within the lungs. The proportions of these components further differ depending on the lung disease. Therefore, different quantification approaches have been proposed to address these variabilities. However, no standardized approach has been developed to date. This article reviews the data evaluating $^{18}$F-FDG PET quantification approaches in lung diseases, focusing on methods to account for variations in lung components and the interpretation of the derived parameters. The diseases reviewed include acute respiratory distress syndrome (ARDS), chronic obstructive pulmonary disease (COPD) and interstitial lung disease such as idiopathic pulmonary fibrosis (IPF). Based on review of prior literature, ongoing research and discussions amongst the authors, suggested considerations are presented to assist with the interpretation of the derived parameters from these approaches and the design of future studies.

Objectives: To raise the awareness of the issues when quantifying uptake of PET tracers in the lungs, focusing on $^{18}$F-FDG.

1. Describe the methods that have been used to quantify $^{18}$F-FDG uptake in the lungs using dynamic PET.
2. Discuss the interpretation of the outcomes from these methods.
3. Provide suggested considerations on quantification of $^{18}$F-FDG uptake in the lungs for future studies.
INTRODUCTION

Motivation for developing PET lung imaging techniques

Respiratory diseases are a significant global health burden that affects millions of people (1, 2). However, treatment options remain limited because pathogenic mechanisms remain poorly understood. The clinical manifestations and severity of lung diseases vary significantly, and the number of clinical biomarkers available to identify aggressive disease phenotypes with accelerated progression is limited. Furthermore, 50% of drugs fail in Phase III trials due to lack of demonstrable efficacy, and respiratory drugs are often the most costly to develop. These facts highlight the need for quantitative biomarkers to select appropriate therapeutic targets and assess the efficacy of novel respiratory therapies (1, 3, 4).

The United States Food and Drug Administration defines a biomarker as "a defined characteristic that is measured as an indicator of normal biological processes, pathogenic processes, or responses to an exposure or intervention, including therapeutic interventions" (5). Traditional clinical measures, such as global lung function, reflect disease severity rather than disease activity. Since inflammation is commonly associated with respiratory diseases, robust molecular biomarkers of pulmonary inflammation could be applied (i) in early-phase clinical pharmacodynamic studies of anti-inflammatory therapies; (ii) as a complement to structural imaging and functional spirometry measures in phenotyping patients who may benefit from more intensive therapy or earlier lung transplant; and (iii) as a tool to improve our understanding of the pathogenic mechanisms of these complex lung diseases.

Molecular imaging approaches such as positron emission tomography (PET) and single photon emission computed tomography could meet the need for non-invasive biomarkers of lung disease (6). Because inflammatory cell recruitment leads to increased glucose utilization in the lungs, 18F-FDG PET has been widely explored as a biomarker of pulmonary inflammation (7-11). However, standardized quantification approaches are lacking. To isolate the 18F-FDG uptake by parenchymal and immune/inflammatory cells, different methods have been proposed to account for regional variations in the fractions of air, blood, and water, which can vary dramatically with each lung disease. Accounting for these variations will apply equally
to new molecular imaging tracers that can measure the activity of specific aspects of lung inflammation or other processes such as fibrosis or endothelial cell activity, as recently reviewed \((12,13)\).

A primary goal for this field is to standardize these approaches for each lung condition. Variability in measured tracer uptake also arises from respiratory motion and differences in reconstruction approaches, among other factors, but these technical issues will be discussed only briefly. Quantification methods for \(^{18}\text{F-FDG}\) lung imaging will be reviewed as it is the most widely studied PET tracer to date and serves as a model for all PET and single photon emission computed tomography tracers used for lung imaging.

### Clinical applications investigated with \(^{18}\text{F-FDG}\) PET imaging

Inflammation characterizes a number of lung diseases, including pneumonia, cystic fibrosis, chronic obstructive pulmonary disease (COPD), acute respiratory distress syndrome (ARDS), asthma, and interstitial lung diseases such as idiopathic pulmonary fibrosis (IPF), among others \((7,8,10,11,14-25)\). As ARDS, COPD, and IPF can cause significant variability in the amounts of air, blood, and water in the lungs (Fig. 1), we will focus our methodology discussion on these diseases. ARDS is characterized by persistent pulmonary neutrophilic inflammation, edema, and pulmonary hemorrhage. These can lead to signal from unbound \(^{18}\text{F-FDG}\) in the increased blood and water fractions as well as specific trapping in neutrophils \((26)\). In COPD, increased numbers of lung neutrophils and macrophages \((1,27-30)\) would be expected to increase the \(^{18}\text{F-FDG}\) signal despite a reduction in measured \(^{18}\text{F-FDG}\) due to larger air fractions and reduced blood volumes as a result of emphysema \((31)\). Finally, IPF is characterized by interstitial pneumonia along with fibrosis in a characteristic subpleural pattern of distribution, leading to reduced air, increased fibrosis, and alterations in blood volume depending on the stage of fibrosis \((32)\). These differences in pathobiology highlight the need to account for the changes in the cellular and fluid composition in the lungs when interpreting any increased lung \(^{18}\text{F-FDG}\) uptake. Exacerbations also represent a confounding factor...
leading to increased lung inflammation and $^{18}$F-FDG uptake; consequently, most studies have been performed in the clinically stable state.

ANALYSIS METHODS AND THEIR APPLICATIONS IN LUNG DISEASES

Quantification approaches for $^{18}$F-FDG

Overview

The $^{18}$F-FDG signal within each PET voxel or predefined region of interest (ROI) in the lungs represents the contribution of activity in parenchymal (i.e. alveolar), airway wall, vascular wall (e.g. endothelial cells) and immune cells (known collectively in this paper as 'lung cells'), as well as blood, and water (i.e. extracellular fluid). A number of factors can degrade the lung cells signal within each voxel, including normal respiratory motion and the presence of air that causes partial volume averaging within each voxel. Furthermore, the contribution of signal from compartments without specific binding, such as blood or water in the lungs, further reduces the signal specificity. The ideal parameter for quantifying $^{18}$F-FDG lung uptake would reflect metabolic activity only from the cells thought to contribute to lung disease progression, namely the lung cells, to determine their pathogenic role. Therefore, investigations have tested different methods to account for the $^{18}$F-FDG signal in the blood and water and to remove the impact of air fraction so that an outcome measure specific to lung cells can be derived. While distinguishing the metabolism of specific cell types, such as parenchymal vs airway cells, would contribute significantly to mechanistic studies of lung disease, these quantification methods alone cannot provide such information. Consequently, finding ways to measure lung cell metabolism specifically will better characterize their role in promoting disease activity and progression.

The methods used to quantify $^{18}$F-FDG uptake in human studies and that will be discussed in this review are summarized in Table 1. Compartmental modelling and Patlak graphical analysis have been used to quantify $^{18}$F-FDG uptake from dynamic images. The standardized uptake value (SUV), with or without dual time-point imaging, and tissue-to-blood ratio have been used for static images. Different approaches have been further applied to reduce the
contribution of background $^{18}$F-FDG signal from blood and water in the lungs as well as reduce partial volume averaging from air in the ROI. For example, kinetic modelling of dynamic PET data can determine the fractional blood volume, $V_B$. PET and CT images have been used to estimate the regional air fraction ($V_A$). Using $V_A$ and $V_B$, the $^{18}$F-FDG uptake in everything that is not air and blood (i.e. lung cells and water), can be measured. These approaches are reviewed below, followed by a discussion of their specific applications in ARDS, COPD and IPF.

**Kinetic approaches**

The Sokoloff method for quantifying $^{18}$F-FDG uptake has served as the basis from which many of the currently used kinetic quantification approaches are derived (33,34). The method was originally developed for measuring brain glucose metabolism, but a key assumption was that the blood volume contribution was negligible relative to the brain parenchymal signal. This was a recognized limitation for applying the method in brain tumors, which have higher $V_B$ than normal brain, necessitating the addition of a blood volume component to the model (35).

With $V_B$ estimated at approximately 0.16 in normal lungs, the blood component has a more substantial effect, both in terms of signal and fractional volume (Fig. 1). Therefore, including $V_B$ in a lung compartment model is even more important.

Furthermore, the lung contains air, which is not the case for other organs. Therefore, an equation (Eq. 1) that accounts for air and blood fractions separately from the other lung components (Fig. 2) has been published and applied in IPF and COPD (21,36):

$$C_M(t) = V_A C_A(t) + V_B C_B(t) + (1 - V_B - V_A) C_T(t)$$  \hspace{1cm} (Eq. 1)

where, for a given ROI, $C_M(t)$ is the measured radioactivity concentration, $C_A(t)$ is the air concentration (which is negligible for intravenously administered tracers like $^{18}$F-FDG), $C_B(t)$ is the blood concentration (derived from the dynamic images or blood samples), and $C_T(t)$ is the concentration in lung cells and water (i.e. everything that is not air or blood). $V_B$ can be estimated from the compartment model. $V_A$ can be determined from the attenuation-corrrection
CT after down-sampling to match the resolution of the PET image (37,38). Therefore, this model enables isolation of the signal from all non-air and non-blood lung components within the ROI ($C_T(t)$). However, when $1 - V_B - V_A$ is less than 0.05 (i.e. in areas of severe emphysema), the accuracy of this correction should be treated with caution (21).

The Patlak graphical analysis is derived from the general compartment model for tracers that are irreversibly trapped in the target tissue (39,40). This analysis provides two parameters: an estimate of the influx rate constant $K_i$, a measure of $^{18}$F-FDG metabolism, and the intercept, which approximates the distribution volume of all the components of the reversible compartment(s). This method is independent of the number of compartments. Intercept normalization of the $K_i$ has been attempted to account for the impact of air on the measurement. However, from Eq. 1, it can be shown that the intercept-normalized Patlak $K_i$ ($K_{in}$) is still influenced by both $V_A$ and $V_B$ (34).

With these methods, after correcting for $V_A$ and $V_B$, the estimated $^{18}$F-FDG uptake comes from the lung cells and water (i.e. everything that is not air or blood). In ILDs and COPD, this is sufficient as the water fraction is small. However, in conditions with increased edema, such as ARDS, the water fraction can be significant. Using independent measures of the tissue fraction, $V_B$, and wet-to-dry ratios (as a measure of water), the normalized $K_i$ determined by the Sokoloff model or a modified four-compartment model that includes a compartment for nonspecific trapping has been used to isolate the lung cell metabolic activity (41-43). These studies confirm the importance of further evaluating modelling approaches that can account for the effects of air, blood and water together to measure the lung cell $^{18}$F-FDG signal specifically.

**Static image quantification approaches**

The standardised uptake value (SUV) is the concentration measured within a region or voxel normalised to the patient weight and the injected activity. This is the most common parameter measured clinically for PET due to its simplicity, despite its dependency on...
metabolism in other organs, body mass and other confounding factors (44,45). The SUV is also affected by air within ROIs. Normalizing it for the air fraction will likely improve its accuracy as a reflection of lung cell metabolic activity (38). Normalization for blood (such as the tissue-to-blood ratio, as explored in a dog model of ARDS (46)) may further improve accuracy $V_B$; however, whether this approach is comparable to correcting for $V_B$ as measured by kinetic analysis or other imaging (such as $^{15}$O-CO scans) remains to be seen.

**Other contributions to errors in $^{18}$F-FDG quantification in the lungs**

Reconstruction algorithms used to generate PET images can have a significant impact on quantification accuracy, including issues with non-linearity and under-convergence when using iterative algorithms (45). The majority of research in this area has focused on detecting lung cancers, which have high signal relative to the lungs. Therefore, further investigation is needed to optimize reconstruction performance for the diffusely distributed, relatively low count activity typically seen in the lungs.

Accurately matching tissue densities between PET and CT images is also essential for accurate PET image attenuation correction and $V_A$ correction. Gross spatial misregistration of the measured attenuation map and PET activity distribution, which frequently occurs at the diaphragm, is known to cause attenuation correction artifacts (47,48). Additionally, changes in lung density from normal respiration between the PET and CT acquisitions can lead to errors in attenuation and $V_A$ correction, introducing additional variability to serial measurements and limiting accurate assessment of the entire lung volume (49). Improved methods for measuring changes in lung density, as well as algorithms to reduce the impact of respiration (50,51) warrant further investigation to improve PET/CT quantification accuracy in lung disease.

**ARDS**

The Patlak graphical analysis and compartmental model for quantifying lung $^{18}$F-FDG uptake have been evaluated most extensively in animal and human models of ARDS
In animal models of ARDS, the Patlak $K_i$ correlated with $^3$H-deoxyglucose uptake in airway cells obtained by bronchoalveolar lavage (52), and $K_i$ normalized for tissue fraction (determined independently by $^{13}$N-$N_2$ scans) correlated with lung neutrophil numbers by histology (53). The $K_i$ determined by the Sokoloff model and by a four-compartment model that includes a water compartment, when normalized for tissue fraction, blood fraction, and wet-to-dry ratios determined independently, further demonstrated regional differences in inflammation related to lung neutrophil numbers in correlating regions (42,43). In a healthy volunteer model of endotoxin-induced acute lung inflammation, both $K_i$ and $K_{iN}$ increased, and both correlated weakly with neutrophil numbers (57). Other lung cells also likely contributed to increased $^{18}$F-FDG uptake after endotoxin instillation, as shown in mouse models (58,59). These data demonstrate that increased $^{18}$F-FDG uptake, quantified by both $K_i$ and $K_{iN}$, are associated with neutrophilic inflammatory responses in these models.

Further validation with compartment modelling has also been performed in ARDS animal models. Independent measures of blood fraction and extravascular lung water obtained with $^{15}$O-CO and $^{15}$O-$H_2$O PET images correlated highly with three-compartmental model-derived estimates from the $^{18}$F-FDG data in a dog model (46). The compartment model estimate of the Patlak $K_i$ also correlated highly with the Patlak-determined $K_i$. Finally, the addition of another compartment for extravascular lung water improved the model fits for estimating lung $^{18}$F-FDG uptake in a sheep model, supporting the applicability of this approach in ARDS (41). Human studies in patients with ARDS have used the Patlak $K_i$ without a correction for lung density or blood fraction but instead have simply compared the $K_i$ in normal versus dense tissue separately across subjects (19,20).

**COPD**

Given the validation of CT for quantifying emphysema (60), $^{18}$F-FDG PET imaging holds great potential for providing additional inflammation-specific information. The $K_{iN}$ has been the primary metric for quantifying $^{18}$F-FDG uptake in COPD and asthma (10,17). $K_{iN}$ correlates negatively with pulmonary function and positively with CT-determined emphysema severity.
$K_{in}$ may also correlate with a chronic bronchitis phenotype (published in abstract form (61)), suggesting the clinical relevance of this parameter. However, $K_{in}$ is not increased in subjects with stable asthma when compared to healthy volunteers (10). Furthermore, no difference in the whole lung $K_i$ was noted between COPD patients and healthy volunteers after accounting for $V_A$ and $V_B$ using compartmental modelling (published in abstract form (36)). The whole-lung SUV normalized for the CT-determined air fraction has also been explored in patients with COPD with emphysema but has not been compared with tissue-based or clinical outcome measures (39). Finally, both infections and allergens frequently trigger asthma and COPD exacerbations. $K_{in}$ likely increases with both triggers, as has been shown in lung transplant recipients with infection (62) and in subjects with asthma after allergen challenge (8,24). Therefore, $^{18}$F-FDG PET scans will need to be obtained during periods of clinical stability to study the accuracy of different quantitative parameters for measuring lung disease-specific inflammation. These studies together highlight the need to continue defining the relationship of the different $^{18}$F-FDG PET quantitative parameters to outcome measures to determine which metrics are the best surrogate measures of inflammation.

**Interstitial Lung Diseases/IPF**

Increased $^{18}$F-FDG uptake has been reported in the lungs of patients with idiopathic pulmonary fibrosis (IPF) using the maximum SUV with or without correction for the air fraction determined by CT (11,22,23,38). A study using dual time-point imaging further demonstrated that persistently increased $^{18}$F-FDG uptake predicted more rapid decline in lung function and higher mortality in patients with IPF (40). Glucose transporter-1 is expressed on erythrocytes and inflammatory cells in lung sections from patients with IPF, with erythrocyte but no inflammatory cell staining at sites of angiogenesis (63). Catabolism genes associated with increased glucose metabolism have increased expression by microarray analysis of human IPF samples (64). These data together support the potential clinical relevance of measuring $^{18}$F-FDG uptake in this disease. However, a modelling analysis using Eq. 1 actually showed decreased $^{18}$F-FDG uptake in the fibrotic areas of the lung compared to areas that appeared...
normal by CT when accounting for $V_A$ and $V_B$ (21) (Fig. 4). These findings still need to be compared to a similar analysis of healthy lungs, but they highlight how these modelling approaches can change the interpretation of $^{18}$F-FDG uptake in IPF. Additionally, improved registration methods are needed to accurately correct for attenuation changes in the periphery, where fibrosis typically occurs. Collectively, these results highlight the need for a gold standard comparator to validate the most relevant $^8$F-FDG parameters for IPF.

**ISSUES AND SUGGESTED CONSIDERATIONS**

The methodological issues discussed above highlight the need for further studies to determine and validate the most appropriate approaches for lung imaging. Based on discussions amongst the authors, the following summary statements were created to capture the key aspects that should be considered for future validation studies:

1) PET measurements of $^{18}$F-FDG concentration in the lung are influenced by the relative volumes of lung cells, air, blood and water.

2) It is essential to understand how the different methodologies account for the relative volumes of air, blood, and water when analyzing PET data to obtain measurements of $^{18}$F-FDG concentration and/or kinetic parameters in the lungs.

3) Relative air, blood and water volumes vary within the lung significantly among respiratory diseases and may depend on disease severity. Without correction, these differences can potentially cause significant variation in the quantified $^{18}$F-FDG PET signal.

4) Although the $K_n$ has been used as the endpoint in many previous publications on lung $^{18}$F-FDG uptake, it does not adequately account for the impact of air and blood.

5) Compartmental modelling is a standard methodology for PET image analysis that can be applied to lung $^{18}$F-FDG data. Using CT data to estimate the air fraction and a kinetic model to account for the blood fraction, it is possible to quantify the glucose metabolic rate for all remaining lung components (i.e. lung cells and water) with $^{18}$F-FDG. The compartment model may need modification to account for increased water (i.e. in ARDS). However, no complete modelling solution that includes air, blood and water fraction corrections has yet been tested.
CONCLUSION

Investigating $^{18}$F-FDG uptake and kinetics in diffuse lung diseases is becoming more common for phenotyping, monitoring disease progression, and assessing the efficacy of novel targeted treatments. For this purpose, ideally $^{18}$F-FDG uptake is measured specifically in the lung cells that contribute to disease pathogenesis. However, regional variations in air, blood, and water fractions can lead to inaccurate estimates of the lung cell tracer concentration. Without accounting for these effects, PET quantification accuracy is compromised and could confound the correct interpretation of the PET parameters in the context of the known biology.

To improve confidence in lung PET quantification, validation of methods to account for air, blood and water fractions using independent techniques would be desirable. For example, the data provided by serial $^{15}$O-CO, $^{15}$O-H$_2$O, and dynamic $^{18}$F-FDG imaging in the same imaging session would provide increased confidence in the estimated blood and water volumes (37). Furthermore, the reproducibility and reliability of these outcome measures will need to be assessed in patients with a range of diffuse lung diseases and in healthy controls. Finally, comparison with clinical information, such as that from CT, lung tissue sampling, or pulmonary function testing, can provide additional context for correctly interpreting PET quantification parameters. These are recommended as examples of future work to promote the standardization of PET analysis methods for lung imaging.

The conclusions laid out in this paper point to the need for a lung imaging collaboration that encourages data and protocol sharing. This will allow validation across the range of lung diseases to be studied, ultimately producing a standardized acquisition and processing methodology. Although not discussed as a focus of this review, these collaborative efforts will also facilitate the evaluation of the most appropriate reconstruction and motion correction algorithms and imaging protocols to optimize lung PET imaging. These efforts will ensure that accurate, reproducible and clinically interpretable images and estimated parameters can be produced together with the requisite clinical validation prior to use in clinical trials of established or novel therapies.

(A) CT image displaying regions of obvious fibrosis (white arrows) and a region of normal appearing tissue (black arrow). Patlak parametric images (B) before air and blood correction, (C) after air fraction correction, and (D) after air and blood fraction correction. All images have been normalized such that they can be shown on the same arbitrary gray scale. The images have been masked to show only the lung. Figure reprinted with permission from reference (21).
Quantification of Lung PET Images: Challenges and Opportunities
