11

12 **Abstract**

13 This paper explores changes in suspended sediment transport and fine sediment storage at  
14 the reach and patch scale associated with the reintroduction of partial LW jams in an  
15 artificially over-widened lowland river. The field site incorporates two adjacent reaches: a  
16 downstream section where LW jams were reintroduced in 2010 and a reach immediately  
17 upstream where no LW was introduced. LW pieces were organised into 'partial' jams  
18 incorporating several 'key pieces' which were later colonised by substantial stands of aquatic  
19 and wetland plants. Reach-scale suspended sediment transport was investigated using  
20 arrays of time-integrated suspended sediment samplers. Patch-scale suspended sediment  
21 transport was explored experimentally using turbidity sensors to track the magnitude and  
22 velocity of artificially generated sediment plumes. Fine sediment storage was quantified at  
23 both reach and patch scales by repeat surveys of fine sediment depth. The results show  
24 that partial LW jams influence fine sediment dynamics at both the patch and reach scale. At  
25 the patch-scale, introduction of LW led to a reduction in the concentration and increase in

1 the time lag of released sediment plumes within the LW, indicating increased diffusion of  
2 plumes. This contrasted with higher concentrations and lower time lags in areas adjacent  
3 to the LW; indicating more effective advection processes. This led to increased fine  
4 sediment storage within the LW compared with areas adjacent to the LW. At the reach-  
5 scale there was a greater increase in fine sediment storage through time within the restored  
6 reach relative to the unrestored reach, although the changes in sediment transport  
7 responsible for this were not evident from time-integrated suspended sediment data. The  
8 results of the study have been used to develop a conceptual model which may inform  
9 restoration design.

## 15 **Introduction**

16 In-stream large wood (LW) can be defined as living or dead wood greater than 1 m in length  
17 and 0.1 m in diameter (Thevenet et al., 1998) and occurs naturally in wooded river systems.  
18 LW influences channel morphology (Montgomery et al., 2003; Wohl, 2016) and performs an  
19 array of important ecological functions (Abbe and Montgomery, 1996; Benke et al., 1985;  
20 Gurnell et al., 2005; Sweka and Hartman, 2006). LW can affect fluvial sediment dynamics  
21 at a range of scales including the reach-scale and the patch-scale (Montgomery et al., 2003).  
22 At the reach-scale, LW may reduce total sediment transport and increase sediment storage  
23 by physically blocking sediment transport (Hart, 2002; Montgomery et al., 2003), generating  
24 local flow divergence (Montgomery et al., 2003), and reducing the shear stress available for  
25 sediment transport by increasing roughness (Assani and Petit, 1995; Manga and Kirchner,

1 2000). The resulting sediment storage can be highly significant (Bilby and Ward, 1989;  
2 Brown et al., 1999; Hart, 2002; Montgomery et al., 2003; Mosley, 1981; Nakamura and  
3 Swanson, 1993; Ryan et al., 2014; Skalak and Pizzuto, 2010). As an example, Elozegi et  
4 al. (2016) projected that basin-wide restoration of LW loading would store 60% of the current  
5 annual sediment yield in four streams draining into the Añarbe Reservoir in Spain. As a  
6 result of this increased storage, river systems with large quantities of LW can have reduced  
7 variability in sediment transport rates (Lancaster et al., 2001; Massong and Montgomery,  
8 2000) and the removal of LW can result in large increases in sediment transport as stored  
9 sediment is released (Beschta, 1979; Bilby, 1981; Heede, 1985; Smith et al., 1993a).

10  
11 At the patch-scale, LW influences the spatial variability of sediment dynamics by inducing  
12 strong spatial variations in shear stress and, therefore, sediment transport and bed material  
13 size (Cherry and Beschta, 1989; Smith et al., 1993b). Flow may be concentrated in areas  
14 adjacent to the LW, increasing local flow velocities (Hygelund and Manga, 2003) and  
15 creating local spatial variation in sediment transport rates and storage (Hilderbrand et al.,  
16 1998; Nakamura and Swanson, 1993; Skalak and Pizzuto, 2010; Trimble, 1997). For  
17 example, He et al. (2009) used two-dimensional hydrodynamic modelling to show that partial  
18 LW jams retarded flow and caused local deposition, whilst the flow in the rest of the channel  
19 was accelerated leading to erosion. While the effects of LW depend on the structural  
20 properties of the jams and the style of channel (Gurnell et al., 2002; Manners et al., 2007),  
21 river channels with abundant LW tend to be more hydrogeomorphologically complex and  
22 store more sediment than wood-depleted rivers and streams (Montgomery et al., 2003).

23 Despite the important contributions of LW to hydrogeomorphological processes and river  
24 health (Erskine and Webb, 2003; Nakamura and Swanson, 1993; Watts, 2006), floodplain  
25 development and river maintenance for navigation and flood risk management have resulted

1 in a long history of LW removal (Wohl, 2014), particularly in lowland rivers (Gippel et al.,  
2 1996). More recently, increasing emphasis on improving the ecological status of water  
3 bodies (European Parliament, 2000) has led to an increase in the re-introduction of LW in  
4 river restoration projects (Cashman, 2014). Of the wood-based restorations in the UK's  
5 National River Restoration Inventory, some 84% were in lowland rivers and channel over-  
6 enlargement (38%) and fine sediment (30%) were the most commonly cited issues affecting  
7 the channels to be restored using LW (Cashman, 2014). Over-enlargement, also known as  
8 re-sectioning or over-widening, is where channel width is artificially increased in order to  
9 increase channel conveyance capacity, but the increase in width reduces sediment transport  
10 capacity so that sedimentation occurs (Brookes, 1985). The resulting fine sediment  
11 deposition can alter channel morphology (Doeg and Koehn, 1994; Nuttal, 1972; Wright and  
12 Berrie, 1987), reduce conveyance capacity (Singer et al., 2008), smother aquatic flora  
13 (Brookes, 1986; Edwards, 1969), and reduce the availability of important habitat for benthic  
14 invertebrates (Petts, 1984; Richards and Bacon, 1994; Schalchli, 1992) and fish (Armstrong  
15 et al., 2003; Sear, 1993; Soulsby et al., 2001).

16  
17 Despite the importance of fine sediment dynamics, and the growing popularity of LW as a  
18 restoration tool within lowland rivers, the majority of research into the influence of LW on  
19 fluvial sediment dynamics has concentrated on naturally occurring LW in high-energy  
20 channels with coarse sediment beds (Montgomery et al., 2003; Wohl and Scott, 2016) with  
21 only a few exceptions (Keller and Swanson, 1979; Skalak and Pizzuto, 2010). The impact  
22 of LW differs between river types (Keller and Swanson, 1979; Wohl and Scott, 2016) and  
23 the lack of research on the impacts of LW on sediment dynamics in lowland rivers therefore  
24 represents an important knowledge gap. Furthermore, restored LW can have different  
25 structural properties to naturally occurring LW, with implications for hydromorphological

1 processes (Cashman, 2014). This paper aims to quantify the influence of reintroduced  
2 partial LW jams on fine sediment dynamics in an artificially over-widened lowland river  
3 reach. In particular, two key research questions are addressed:

- 4 1. How has the introduction of partial LW jams influenced the transport of suspended  
5 sediment, at both the reach- and patch-scale?
- 6 2. How has the introduction of partial LW jams influenced the storage of fine sediment  
7 (sand and silt), at both the reach- and patch-scale?

8 Based upon findings of previous studies of naturally occurring LW in high energy channels,  
9 we hypothesised that, until a new equilibrium form is achieved, the reintroduced LW would  
10 reduce reach-scale suspended sediment transport, increase reach-scale fine sediment  
11 storage, and increase patch-scale variability in both suspended sediment transport and fine  
12 sediment storage.

13

## 14 **Methods**

### 15 ***Field site***

16 The field site for this project was a 160 m reach of a lowland chalk stream, located at an  
17 altitude of approximately 12 m AOD on the River Bure in North Norfolk, UK (Figure 1). The  
18 majority of the upstream catchment land use is arable agriculture and the floodplain at the  
19 study reach is wet alder (*Alnus glutinosa*) woodland. Prior to 2010, LW falling into the  
20 channel had been removed as part of regular river maintenance and the channel was heavily  
21 silted as a result of historic over-widening and dredging related to mill developments dating  
22 back to the 18<sup>th</sup> Century. The bankfull channel width and mean depth were approximately  
23 10 m and 1 m respectively, the bed slope along the reach was 0.0017, and the bed material  
24 consists of fine gravel overlain by up to 0.8 m of sand and silt.

25

1 In November 2010, river restoration works were performed on the downstream 60 m of the  
2 field site (by the UK National Trust) in response to concerns over the channel's ecological  
3 status. The overall aim of the project was to improve the physical habitat by reinstating in-  
4 stream LW features and hence natural processes. Riparian trees (Alder) were felled into  
5 the river from the wooded riparian zone. A total of 22 'key pieces' (whole felled trees,  
6 excluding rootwads, between 8 and 19 m in length) were organised into seven jams (Table  
7 1 and Figure 1) and secured by anchoring to either the adjacent bank or the channel bed.  
8 All seven jams were classed as 'partial jams' (Gregory et al., 1985) since they did not span  
9 the full channel width. Following their introduction, the LW jams were colonised by aquatic  
10 plants, which included floating plants (e.g. *Lemna minor*), emergent shallow water species  
11 (e.g. *Nasturtium officinale*, *Apium nodiflorum*) and marginal emergent species (e.g. *Phalaris*  
12 *arundinacea*, *Epilobium hirsutum*). The field site consisted of the 60 m restoration reach  
13 where these partial LW jams were introduced ("R") and a further 100 m reach directly  
14 upstream with no LW jams ("NR"; Figure 1). Figure 2 presents the sampling schedule for  
15 the study within the context of the hydrological time series from a gauging station 2.5 km  
16 downstream of the research site.

### 17

### 18 ***Time-integrated sampling of suspended sediment transport***

19 To investigate the impact of introducing partial LW jams on reach-scale suspended sediment  
20 transport rates, four arrays of time-integrated suspended sediment samplers were installed  
21 in May 2010, five months prior to the introduction of the LW. Each array consisted of three  
22 passive samplers based upon the 'rocket' design of Phillips et al. (2000). Within each array  
23 the three samplers were spaced evenly across the width of the channel and secured to the  
24 bed at 0.6 of the flow depth at the mean daily flow ( $Q_{31}$ ) following Phillips *et al.* (2000) using  
25 steel uprights. As illustrated in Figure 1, two arrays were located upstream of where LW was

1 introduced: one at the upstream extent of the NR reach ('U1') and the other at the transition  
2 between the NR reach and the R reach ('U2'). A further array was positioned within the  
3 restored section, approximately halfway along the R reach ('D1') and the other downstream  
4 of the R reach ('D2'). The contents of each of the arrays were emptied, dried and weighed  
5 at the end of seven contiguous sampling periods (Figure 2). The first two sampling periods  
6 were prior to the LW introduction (May-July 2010 and July-November 2010) and the  
7 remaining five sampling periods followed the LW introduction (between November 2010 and  
8 July 2012). Mean dry mass was calculated for each array (n = 3 samplers) for each sampling  
9 period, and divided by the number of days in the sampling period to give the mean rate of  
10 sampled suspended sediment transport ( $\text{g day}^{-1}$ ).

11

### 12 ***In-situ experimental assessment of patch-scale suspended sediment transport***

13 To investigate the impact of individual LW jams on the transport of suspended sediment  
14 plumes at the patch-scale, in-situ experiments were designed to record the downstream  
15 transport of individual suspended sediment plumes created by controlled releases of silt  
16 following Harvey and Clifford (2010). Similar tracer experiments have been used to explore  
17 hydraulic habitat and retention in different channel types (Milner and Gilvear, 2012). Figure  
18 3 illustrates the experimental set up for the release and measurement of the suspended  
19 sediment plumes. Artificial plumes were generated using 100 ml containers of fine sediment  
20 ( $D_{50} \approx 0.25$  mm) collected from channel margins, spaced 0.1 m apart across the entire width  
21 of the flow. The number of containers used varied (48-103) to account for variations in flow  
22 width (4.8m-10.3m), ensuring consistent release concentrations at each cross section. The  
23 containers were emptied into the water simultaneously 5 m upstream of a cross-sectional  
24 array of turbidity sensors. Five infrared turbidity sensors (Left – "L", Left Centre – "LC",  
25 Centre – "C", Right Centre – "RC", and Right – "R") were evenly spaced across the width of

1 the channel cross-section. They were secured to the channel bed at a height of 0.6 of the  
2 water depth using steel uprights. Turbidity sensors were connected to a data logger,  
3 recording data at a frequency of 5 Hz for a period of 3 minutes following the release of a  
4 sediment plume. A similar experimental design has been applied in a lowland channel with  
5 relatively low flow velocities and shallow water depths (Harvey and Clifford, 2010). Turbidity  
6 was converted to sediment concentration ( $\text{mg L}^{-1}$ ) by calibration ex-situ with known  
7 concentrations of sediment collected from the field site ( $D_{50} \approx 0.25$  mm). Relationships  
8 between voltage output and suspended sediment concentration were quantified for each  
9 sensor by fitting polynomial regression curves ( $R^2 > 0.99$  for all five sensors). Plume  
10 experiments were performed in triplicate at three cross-sections (Figure 1) at three times  
11 throughout the study period: once before the LW was introduced (August 2010), and twice  
12 following the LW introduction (April 2011 and July 2012; Figure 2). During all three  
13 experimental periods river discharges were between the  $Q_{75}$  and the  $Q_{50}$  (Figure 2). The  
14 three cross-sections were located as follows: one within the NR reach ('NR') and two within  
15 the R reach where LW was introduced in November 2010 ('R<sub>A</sub>' and 'R<sub>B</sub>').

16  
17 Suspended sediment time series from the plume experiments were smoothed using a  
18 moving average window of two seconds in order to focus analysis on the characteristics of  
19 released sediment plumes rather than turbulence-driven sediment suspension events.  
20 Characteristics of sediment plumes were assessed by plotting measured sediment  
21 concentration against time and by calculating the peak sediment concentration and time to  
22 peak following release, following Harvey and Clifford (2010). These data were used to  
23 explore differences before and after LW introduction both for cross-sections and for  
24 individual points within cross-sections.

25

1 **Measurement of fine sediment bed storage**

2 To quantify the impact of introduced LW jams on the deposition and storage of previously  
3 suspended sediment at both the reach- and patch-scale, surveys of fine (silt and sand)  
4 sediment depth were repeated six times throughout the sampling period (Figure 2). Two  
5 surveys were conducted before the introduction of LW and four surveys following LW  
6 introduction. For each survey fine sediment depth measurements were taken at 34 equally-  
7 spaced (5 m) cross-sections – 13 within the R reach and a further 21 in the NR reach. At  
8 each cross-section, four sample points were spaced equally across the width of the channel.  
9 At each sample point, a 3 mm diameter pin, 1 m in length, was pushed into the riverbed until  
10 it came into contact with underlying coarse substrate (Lisle and Hilton, 1992). This provided  
11 measurements of fine sediment depth at a total of 136 points during each of the survey  
12 periods: 52 in the R reach and 84 in the NR reach, with 36 of the points in the R reach in  
13 patches within LW jams and the remaining 16 points in the R reach in patches adjacent to  
14 LW jams. These data were used to explore differences in fine sediment storage before and  
15 after LW introduction, at both the reach- and patch-scale, and the trajectory of any changes  
16 over the sampling period.

17

18 **Data analysis**

19 Many of the collected data sets did not meet the assumptions of parametric tests and  
20 therefore non-parametric statistical tests were applied. Correlations between variables were  
21 assessed using Spearman's Rank, differences between group averages were explored  
22 using Mann Whitney U and Kruskal-Wallis H tests, and differences in the variability within  
23 groups were explored using Levene's test. Confidence levels  $\geq 90\%$  ( $p \leq 0.1$ ) were applied  
24 in all cases. Analyses were undertaken in Minitab 17 and Microsoft Excel 2010.

25

## 1 **Results**

### 2 ***Influence of LW on reach-scale suspended sediment transport***

3 The rate of suspended sediment transport at each of the sampling arrays throughout the  
4 period of record is given in Figure 4. The sampled rate of sediment transport ranged from  
5 0.0061 g day<sup>-1</sup> to 0.0944 g day<sup>-1</sup> over the study. There was a statistically significant  
6 difference between the seven sampling periods (Kruskal-Wallis P = 0.002), but no significant  
7 difference between the four sampling locations (Kruskal-Wallis P = 0.712). Whilst the rate  
8 of suspended sediment transport measured at arrays downstream of LW was significantly  
9 higher following LW introduction (median = 0.0546 g day<sup>-1</sup>) compared to before (median =  
10 0.0188 g day<sup>-1</sup>; Mann-Whitney P = 0.077), a similar trend was also identified at arrays  
11 upstream of LW (before median = 0.0248g day<sup>-1</sup>; after median = 0.0587 g day<sup>-1</sup>; Mann-  
12 Whitney P = 0.040). Thus, while an increase in sediment transport following LW  
13 reintroduction is apparent, it occurs both upstream and downstream of the LW.

### 14 15 ***Influence of LW on patch-scale suspended sediment transport***

16 Comparisons between suspended sediment plume transport characteristics at cross-  
17 sections R<sub>A</sub> and R<sub>B</sub> before (2010) and after (2011) the LW introduction are given in Figure  
18 5. There was no significant difference in peak sediment concentrations after the LW  
19 introductions at either R<sub>A</sub> (median before = 0.138 g L<sup>-1</sup>; after = 0.109 g L<sup>-1</sup>; Mann-Whitney P  
20 = 0.927) or R<sub>B</sub> (median before = 0.074 g L<sup>-1</sup>; after = 0.095 g L<sup>-1</sup>; Mann-Whitney P = 0.232).  
21 There was also no significant change in times to peak following the LW introduction at R<sub>A</sub>  
22 (median before = 20.4 s, after = 27.4 s, Mann-Whitney P = 0.140), but there was a reduction  
23 in times to peak at R<sub>B</sub> (median before = 92.6 s, after = 78.0 s, Mann-Whitney P = 0.054).  
24 Despite limited changes in average plume characteristics following LW introductions, there  
25 were significant increases in the variability of plume characteristics at both cross-sections:

1 both for peak concentrations ( $R_A$  std. dev. before =  $0.054 \text{ g L}^{-1}$ ,  $R_A$  std. dev. after =  $0.096 \text{ g}$   
2  $\text{L}^{-1}$ , Levene's test  $P = 0.054$ ;  $R_B$  std. dev. before =  $0.025 \text{ g L}^{-1}$ ,  $R_B$  std. dev. after =  $0.080 \text{ g L}^{-1}$ , Levene's test  $P = 0.018$ ); and times to peak ( $R_A$  std. dev. before =  $3.98 \text{ s}$ ,  $R_A$  std. dev.  
3 after =  $21.83 \text{ s}$ , Levene's test  $P = 0.002$ ;  $R_B$  std. dev. before =  $16.62 \text{ s}$ ,  $R_B$  std. dev. after =  
4  $37.06 \text{ s}$ , Levene's test  $P = 0.007$ ).

6  
7 The spatial organisation of plume characteristics is explored for individual cross-sections in  
8 Figure 6. At cross-section NR, where no wood was present, highest sediment  
9 concentrations were in the centre of the channel with slightly longer times to peak towards  
10 the left bank for two out of three experiments. In the 2012 experiment this pattern was  
11 disrupted when the growth of emergent vegetation adjacent to the left hand bank reduced  
12 the magnitude and velocity of the sediment plume on the left side of the channel. At the two  
13 cross-sections where LW was introduced, the spatial pattern of sediment concentration and  
14 time to peak was reorganised following LW introduction. At cross-section  $R_A$  prior to LW  
15 introduction, peak concentrations were relatively similar across most of the channel but with  
16 lower concentrations and longer time to peak at the margins. Following LW introduction  
17 peak concentrations decreased within the LW and increased in areas adjacent to the LW.  
18 There was also an increase in the time to peak within the LW. At cross-section  $R_B$  prior to  
19 LW introductions, peak concentrations and times to peak were similar across the channel  
20 width. Following LW introductions, the sediment plumes increased in magnitude and  
21 velocity in areas adjacent to the LW but remained lower in areas within the LW.

22  
23 The changes to the sediment plumes are illustrated in greater detail for an example cross  
24 section ( $R_A$ ) in Figure 7. A progressive differentiation between sediment traces within and  
25 adjacent to LW is evident following the LW introduction. Prior to LW introduction, the shape

1 of sediment traces was similar across the channel width. Following LW introduction, the  
2 within-wood sensors displayed lower concentrations and longer time lags indicating less  
3 effective transmission of sediment plumes. In contrast, traces from sensors positioned  
4 adjacent to the LW exhibited similar or higher peak concentrations and shorter lag times  
5 following LW introduction.

### 7 ***Influence of LW on reach-scale and patch-scale fine sediment storage***

8 Figure 8a illustrates that both the R and NR reaches experienced increases in fine sediment  
9 depth following LW introduction. However, the 95 mm increase in the median depth of the  
10 R reach (before = 0.175 m, after = 0.270 m, Mann-Whitney P = 0.02) was greater than the  
11 35 mm increase in the median depth of the NR reach (before = 0.075 m, after = 0.110 m,  
12 Mann-Whitney test P < 0.001). Fine sediment depths also became more variable in the R  
13 reach (SD before = 0.166 m, std. dev. after = 0.186 m, Levene's test P = 0.074) but there  
14 was no increase in the variability within the NR reach (std. dev. before = 0.110 m, std. dev.  
15 after = 0.138 m, Levene's test P = 0.480).

16  
17 Patch-scale sediment storage at points within and adjacent to the LW jams in reach R are  
18 presented in Figure 8b. Prior to LW introductions (2010) there was no significant difference  
19 between fine sediment storage in areas where LW was later introduced and the adjacent  
20 channel areas (wood median = 0.180 m, adjacent median = 0.155 m, Mann Whitney P = 1),  
21 but following LW introductions (2011) these LW patches became associated with  
22 significantly higher sediment storage than adjacent areas (wood median = 0.320 m, adjacent  
23 median = 0.170 m, Mann Whitney P = 0.008). This change reflects an increase in fine  
24 sediment storage in patches where LW was introduced following the LW introductions  
25 (before median = 0.180 m, after median = 0.320 m, Mann Whitney P < 0.001), while no

1 significant change was identified for patches adjacent to the LW (before median = 0.155 m,  
2 after median = 0.170 m, Mann Whitney P = 1).

3

4 The trajectories of these reach-scale and patch-scale changes in fine sediment storage are  
5 explored in Figure 9. Positive trends between sediment depth and time were observed for  
6 both the R reach and the NR reach, and for points within the R reach both within and  
7 adjacent to the wood. However, while there was a general trend for sediment accumulation  
8 across the whole study site, the gradient of the trend is steeper in the R reach than the NR  
9 reach, and steeper at the points within the wood than at the points adjacent to the wood.  
10 Mean sediment accumulation in the R reach is at an average rate of 67 mm year<sup>-1</sup> whilst the  
11 mean accumulation in the NR reach is 26 mm year<sup>-1</sup>. Similarly, mean sediment  
12 accumulation at the points within the wood is at a rate of 77 mm year<sup>-1</sup>, while mean  
13 accumulation at points adjacent to the wood is just 42 mm year<sup>-1</sup>.

14

## 15 **Discussion**

16 The reintroduced partial LW jams altered suspended sediment dynamics at both the patch-  
17 and reach-scale in the study river. At the patch-scale, results of the controlled sediment  
18 release experiments illustrate differences in suspended sediment transport within LW and  
19 adjacent patches, indicating spatial variability in mixing mechanisms at moderate flow levels  
20 (Q<sub>50</sub> – Q<sub>75</sub>). Within LW patches, sediment plumes show longer times to peak and lower  
21 peak sediment concentrations, indicating a dominance of diffusion processes whereby the  
22 sediment cloud spreads out vertically through the water column and/or transversely towards  
23 the banks from areas of high to low concentration (Rutherford, 1994). By contrast, in areas  
24 of flow concentration adjacent to the LW, shorter times to peak and higher peak turbidity  
25 values suggest more effective advection processes whereby the plume is moved

1 downstream as a coherent body with less significant changes in concentration. This patch-  
2 scale variability in suspended sediment transport at moderate flow levels is reflected in  
3 differences in fine sediment storage between patches within LW and patches adjacent to  
4 LW. In turn, increased sediment storage within the LW signals that the dispersion processes  
5 lead to retention of sediment within the LW jam, while the maintenance of channel depth in  
6 patches adjacent to the LW reflects more efficient transport of sediment. Increases in spatial  
7 variability of sediment transport and storage caused by the reintroduced LW in this artificially  
8 over-widened lowland river channel reflect previous findings from studies of naturally  
9 occurring LW in higher energy environments (Montgomery et al., 2003; Nakamura and  
10 Swanson, 1993; Wohl and Scott, 2016) and, by creating a more diverse array of physical  
11 habitats for aquatic organisms, could help to address legislative requirements like the EU  
12 Water Framework Directive (European Parliament, 2000).

13  
14 At the reach-scale, a measureable reduction in sediment transport was not evident in time-  
15 integrated suspended sediment data despite fine sediment storage increasing in both the R  
16 and NR reaches throughout the sampling period. It is possible that short-term modification  
17 of flow patterns in the R reach resulted in local sediment mobilisation during or immediately  
18 following restoration in the R reach. However, given the same trends are observed in both  
19 the R and NR reaches, it likely reflects the influence of catchment supply processes and the  
20 supply-limited nature of suspended sediment dynamics (Amos et al., 2004; Asselman, 1999;  
21 Einstein and Chien, 1953; Nicholas et al., 1995). Fine sediment storage did, however,  
22 increase at a faster rate within the restored reach relative to the unrestored reach. This  
23 demonstrates that the LW did reduce reach-scale sediment transport enough to encourage  
24 net sediment deposition, reflecting previous findings within higher energy channels (Bilby  
25 and Ward, 1989; Elosegi et al., 2016; Mosley, 1981; Nakamura and Swanson, 1993).

1 However, the reduction in reach-scale sediment transport responsible for increased storage  
2 was not significant in relation to supply-driven variability in transport rates, findings which  
3 differ to those from higher energy systems (Lancaster et al., 2001; Massong and  
4 Montgomery, 2000).

5  
6 It is important to note that extensive stands of wetland plants were associated with the  
7 reintroduced LW jams at this study site. This characteristic may be expected for other  
8 lowland rivers subject to restoration as management of the riparian zone can promote the  
9 growth of aquatic plants by reducing shading and elevating nutrient levels (Bunn et al., 1998;  
10 Duarte, 2012; Wersal and Madsen, 2011).

11  
12 The results from this study can be used to develop a model of the influence of restored,  
13 vegetated, partial LW jams on suspended sediment dynamics in artificially over-widened  
14 lowland rivers, which includes two form-process feedback loops (Figure 10). The first occurs  
15 where the increase in local hydraulic roughness (Assani and Petit, 1995) and the physical  
16 barrier caused by a partial LW jam (Montgomery et al., 2003) reduces sediment transport  
17 through the LW, causing more fine sediment accumulation within the LW. This sediment  
18 accumulation acts to further increase local hydraulic roughness and the physical barrier  
19 created by the jam. Growth of aquatic plants around the LW, as characteristic of our study  
20 site and lowland rivers more generally, may amplify this process by contributing additional  
21 'ecosystem engineering' capacity (Gurnell, 2014). The second form-process feedback loop  
22 occurs where the increased local hydraulic roughness and physical barrier created by the  
23 LW jam increases the proportion of flow diverted around the jam and therefore increases  
24 local shear stress and sediment transport around the jam (Hilderbrand et al., 1998;  
25 Nakamura and Swanson, 1993; Trimble, 1997). Elevated sediment transport around the

1 jam acts to maintain the channel thalweg around the LW so that further increases in the  
2 obstruction caused by the LW may be counter-balanced by increased sediment transport  
3 around the LW. Based on these results, it can be hypothesised that, over time, these  
4 processes will result in the previously over-widened channel becoming narrower as the LW  
5 jams fill with sediment and become permanent morphological features. If this occurs, the  
6 channel should eventually achieve a new equilibrium form with narrower channel  
7 dimensions to support sufficient sediment transport capacity and reduce the likelihood of  
8 further aggradation. Further long-term monitoring would be required to assess these  
9 changes.

10

## 11 **Conclusion**

12 This paper shows patch and reach scale alterations to the sediment dynamics of an  
13 artificially over-widened lowland river as induced by reintroduced partial LW jams. The  
14 findings make an important contribution to the evidence base for using LW in lowland river  
15 restoration, where limited research on LW impacts on fine sediment dynamics has been  
16 performed. We show that reintroduced LW induces patch-scale changes in mixing  
17 mechanisms, altering local sediment dynamics leading to a combination of increased  
18 storage around LW and increased transport in intervening areas. At the reach-scale the LW  
19 caused aggradation, suggesting that sediment retention within LW jams exceeded the rate  
20 of sediment removal from adjacent areas of flow concentration. However, the influence that  
21 this had on reach-scale suspended sediment transport was not measurable amongst the  
22 supply-driven variability observed over the sampling period. The results of this study are  
23 directly relevant to LW-based restoration design within over-widened lowland river channels  
24 but may also provide a useful framework for assessing LW-based restoration design within  
25 other channel types, and for understanding how naturally occurring LW jams influence

1 lowland river channels. Further research is now required to assess the influence of different  
2 types of LW jams, including naturally occurring LW, on fine sediment dynamics in lowland  
3 channels; to assess the influence of LW on suspended sediment transport across varying  
4 discharges; and to provide longer-term evaluation of the trajectory of change in restored  
5 channels following wood reintroductions.

## 7 **Acknowledgements**

8 With special thanks to Dave Brady and the UK National Trust for access to the field site,  
9 providing background information and postponing the restoration to allow for baseline data  
10 collection. This research was supported by a British Society for Geomorphology Research  
11 Grant ('Assessing the long term influence of wood on the hydromorphology of a lowland UK  
12 river') and a University of the West of England Early Career Research Starter Grants  
13 scheme. The paper is dedicated to Dave Brady, the driving force behind this project.
