THE ROLE OF THE AGENT’S OUTSIDE OPTIONS
IN PRINCIPAL-AGENT RELATIONSHIPS*

Abstract

We consider a principal-agent model of adverse selection where, in order to trade with the principal, the agent must undertake a relationship-specific investment which affects his outside option to trade, i.e. the payoff that he can obtain by trading with an alternative principal. This creates a distinction between the agent’s ex ante (before investment) and ex post (after investment) outside options to trade. We investigate the consequences of this distinction, and show that whenever an agent’s ex ante and ex post outside options differ, this may equip the principal with an additional tool for screening among different agent types, by randomizing over the probability with which trade occurs once the agent has undertaken the investment. In turn, this may enhance the efficiency of the optimal second-best contract.

JEL Classification: D21, L14.

Keywords: adverse selection, randomization, type-dependent outside options.

*We thank the associate editor and two anonymous referees for suggestions that have helped improve the paper. We have also benefitted from the comments of Fabrizio Adriani, Roman Inderst, Ian Jewitt, Bruno Jullien, Thomas Mariotti, In-Uck Park, Francesco Squintani, Max Steuer, Thomas von Ungern-Sternberg and seminar participants at LSE and the University of Lausanne. 1 Introduction

In many forms of bilateral exchange, one party has to undertake relationship-specific investments before trade can occur with their partner. An important consequence of such specific investments is that they typically change the investing party’s outside option to trade, namely the payoff that he would obtain by trading with an alternative partner. For example, a firm that tailors its machinery in order to produce a specific widget required by a certain buyer, will change its production possibilities when trading with alternative buyers whose requirements need not be the same.\(^1\)

A key distinction therefore exists between the firm’s \(\text{ex ante}\) outside option, before the relationship-specific investment is undertaken, and their \(\text{ex post}\) outside option, after the investment has occurred. This paper investigates the consequences of this distinction in principal-agent models of adverse selection, where the agent’s type is his private information, and both parties are risk neutral. We show that whenever an agent’s \(\text{ex ante}\) and \(\text{ex post}\) outside options differ, this may equip the principal with an additional tool for screening among different agent types, by randomizing over the probability with which trade occurs once the agent has undertaken the specific investment. In turn, this may enhance the efficiency of the optimal second-best contracts.

This paper contributes to the literature on mechanism design when agents have type-dependent outside options (Lewis and Sappington 1989, Maggi and Rodriguez-Clare 1995, Jullien 2000). The literature on adverse selection identifies several cases in which the optimal mechanism can involve randomization, such as when agents have different levels of risk aversion (Stiglitz 1982, Arnott and Stiglitz 1988, Brito \textit{et al} 1995), when the agent’s type-space is multi-dimensional (Baron and Myerson 1982, Rochet 1984 and Thanassoulis 2004), or when randomization might allow non-monotonic allocation schedules to become incentive compatible (Strausz 2006). A further rationale for randomization is presented by Calzolari and Pavan (2006), who show that, in principal-agent problems with sequential contracting, randomization may be optimal, since it allows one principal to hide information from another principal. We add to the literature by considering situations where relationship-specific investments affect the agent’s future prospects, so that his type-dependent \(\text{ex ante}\) and \(\text{ex post}\) outside options differ. This provides a novel rationale of why randomization may be optimal in principal-agent settings.

The remainder of the paper is organized as follows. In Section 2 we develop the principal-agent model. Section 3 solves for the optimal second best contracts. Section 4 discusses the efficiency consequences of having both types of outside option and also addresses possible extensions. All proofs and a numerical example are in the Appendix.

2 Model

\textbf{Preliminaries} We consider a principal-agent model with a principal \(P\) and an agent \(A\), who contract over the production of output, \(q\). Production is assumed to be observable and verifiable. The agent’s marginal cost of production, \(\theta\), which defines his type, is not observed by the principal, and we assume

\(^1\)This phenomenon is not confined to bilateral exchange between firms. Consider a traveller who wants to travel from A to B at 8pm on a given day. The traveller can choose whether to travel by train or bus. The specific investment undertaken by the traveller in order to access a certain type of travel takes the form of him being physically present at a particular location – the bus or train station – at a particular time. While from an \(\text{ex ante}\) perspective the traveller’s outside option to catching the 8pm bus would be to take the 8pm train, once he has made the specific investment of arriving at the bus station prior to 8pm, his \(\text{ex post}\) outside option to catching the 8pm bus will be quite different. While he may for example catch the 9pm train, the 8pm train has been ruled infeasible by his earlier specific investment.
\( \theta \in \{ \theta_H, \theta_L \} \), where \( \theta_H > \theta_L > 0 \), and \( \text{prob}(\theta = \theta_H) = \lambda \). In order to trade with the principal, the agent must undertake a relationship-specific investment, with cost normalized to zero. The agent’s decision to undertake the investment is observable and verifiable. A contract between the principal and the agent is denoted \( \{ \phi, \pi, q, T \} \), where \( \phi \in \{0,1\} \) specifies whether the agent must undertake the investment\(^2\), \( \pi \in [0,1] \) denotes the probability with which trade occurs between the parties, \( q \in [0, \overline{q}] \) denotes the output that the agent must produce in case of trade, and \( T \in \mathbb{R}^+ \) indicates the payment from the principal to the agent (independent of whether trade actually occurs or not). We assume trade can only occur if the agent has made the relationship-specific investment so that if \( \phi = 0 \), \( \pi = 0 \).\(^3\)

The principal’s problem consists of designing the optimal menu of contracts from which the agent makes his preferred choice. The revelation principle states this search can be confined to the set of direct revelation mechanisms, whereby the agent is requested to report his type and is offered a contract that is contingent upon this report. The timing of actions is then as follows.

\( t=0 \) \( P \) offers \( A \) a menu of contracts \( M = \{ M_H, M_L \} \), where \( M_i = \{ \phi_i, \pi_i, q_i, T_i \} \) is the contract offered to the agent when his reported type is \( \theta_i, i = H, L \).

\( t=0.5 \) If \( A \) accepts \( M_i \) and \( M_i \) specifies \( \phi_i = 1 \), \( A \) undertakes the relationship-specific investment.

\( t=1 \) Conditional on \( \phi_i = 1 \), trade occurs with probability \( \pi_i \), in which case \( A \) produces \( q_i \). With probability \( 1 - \pi_i \) trade between \( A \) and \( P \) does not occur. If \( \phi_i = 0 \), trade between \( A \) and \( P \) does not occur with certainty.

\( t=1.5 \) Provided that he has respected the terms of the contract, \( A \) receives \( T_i \).

Without loss of generality we restrict attention to contracts that always induce truthtelling and participation by the agent.

**Agent’s Ex ante and Ex post Outside Options** If the agent does not accept the principal’s contract, or if his contract prescribes \( \phi_i = 0 \), then the agent does not undertake any relationship-specific investment, and obtains a payoff \( B_i \geq 0 \) from alternative trade, where \( i = H, L \). This defines the agent’s ex ante outside option. Importantly, we allow for the possibility that ex ante outside options differ across types, so that \( B_H \neq B_L \). If the agent undertakes the relationship-specific investment, but trade between the parties does not occur, then the agent obtains a payoff \( C_i < B_i \) from alternative trade. \( C_i \) captures the agent’s ex post outside option, namely the value of his trading prospects with alternative principals, after having undertaken the relationship-specific investment with the previous principal. Ex post outside options may also be type-dependent, so that \( C_H \neq C_L \). The expression \( B_i - C_i > 0 \) reflects the loss in terms of the agent’s alternative trading prospects from undertaking the relationship-specific investment, which tailors his production to the principal’s needs. We refer to this as the opportunity cost of randomization, since this cost is only incurred when \( \pi_i < 1 \).

**Payoffs** Both parties are assumed to be risk neutral with respect to monetary transfers and production. If a type \( \theta_i \) agent accepts a contract \( \{ \phi_i, \pi_i, q_i, T_i \} \), his net expected utility is,

\[
    u(\theta_i) = T_i + \phi_i \left\{ -\theta_i \pi_i q_i + (1 - \pi_i) C_i - B_i \right\}.
\]  

\(^2\)Allowing the contract to specify \( \phi \) enables us to restrict attention to contracts that are always accepted by the agent. We thank an anonymous referee for providing this suggestion.

\(^3\)By restricting attention to \( \phi \in \{0,1\} \) we rule out the possibility of the principal randomizing over \( \phi \). This is done to shorten the exposition of our results. The possibility of randomization over \( \phi \) is discussed in section 4.
The principal’s expected payoff is $U_P = \phi_i \pi_i v q_i - T_i$, where $v > \theta_H$. Let $u_i$ denote the utility obtained by a type $\theta_i$ agent when he truthfully declares his type. From (1), holding constant all other dimensions of the contract offered to type $\theta_i$, there is a one-to-one relation between $T_i$ and $u_i$. In what follows we will therefore characterize a contract as $M_i = \{\phi_i, \pi_i, q_i, u_i\}$. Finally, we denote $\theta_H - \theta_L$ as $\Delta \theta$, $C_H - C_L$ as $\Delta C$, $B_H - B_L$ as $\Delta B$ and $u_H - u_L$ as $\Delta u$.

3 Results

The participation constraint for a type $\theta_i$ agent is $u_i = T_i + \phi_i [-\theta_i \pi_i q_i + (1 - \pi_i) C_i - B_i] \geq 0$. The incentive compatibility constraints which ensure agents find it optimal to declare their true type are,

$$IC_H : u_H \geq u_L + \phi_L [-\pi_L q_L \Delta \theta + (1 - \pi_L) \Delta C - \Delta B].$$

$$IC_L : u_L \geq u_H + \phi_H [\pi_H q_H \Delta \theta - (1 - \pi_H) \Delta C + \Delta B].$$

Suppose full information contracts are offered so that $\phi_i = \pi_i = 1$, $q_i = \overline{q}$, and $u_i = 0$ for $i = H, L$. Constraint $IC_H$ becomes, $0 \geq -\overline{q} \Delta \theta - \Delta B$, and $IC_L$ becomes, $0 \geq \overline{q} \Delta \theta + \Delta B$. We focus on the more intuitive case in which $\overline{q} \Delta \theta + \Delta B > 0$ so that $\theta_L$ types have incentives to overstate their costs and mimic $\theta_H$ types. This is embodied in assumption A1 below.\(^4\) To ensure that under full information the optimal contract prescribes $\phi_i = \pi_i = 1$, $q_i = \overline{q}$ for both types, assumption A2 below is required.

A1: $\overline{q} \Delta \theta + \Delta B > 0$

A2: $\overline{q} (v - \theta_i) \geq B_i$, $i = H, L$

Our first result provides a partial characterization of type $\theta_H$’s optimal contract whenever $\theta_H$ agents are required to undertake the relationship-specific investment.

Lemma 1: It is never optimal for the principal to offer $\phi_H = 1$ in conjunction with $\pi_H$ and $q_H$ satisfying,

$$\pi_H q_H \Delta \theta - (1 - \pi_H) \Delta C + \Delta B < 0.$$  \hspace{1cm} (2)

Under A1 the full information contracts would violate $IC_L$. By offering type $\theta_H$ agents a contract such that $\pi_H q_H \Delta \theta - (1 - \pi_H) \Delta C + \Delta B = 0$, the principal ensures both that $IC_L$ is satisfied and that no rents are offered to $\theta_L$ agents. Offering $\theta_H$ agents a contract such that (2) holds would only increase the distortions of $\pi_H$ and/or $q_H$ from their full information values (1 and $\overline{q}$ respectively) without generating any gain for the principal. This is essentially the rationale for Lemma 1.

An implication of Lemma 1 is that the participation constraint of type $\theta_L$ will not bind at the optimum. This is because, given type $\theta_H$’s participation, $IC_L$ implies $u_L \geq u_H \geq 0$. In what follows, we therefore allow $IC_L$ to hold with equality, let $u_H = 0$, and ignore constraint $IC_H$. We then later verify that the solution of the relaxed problem indeed satisfies $IC_H$. The principal’s problem then is,

$$\max_{\phi_i \in \{0,1\}, \pi_i \in \{0,1\}, q_i \in (0,1), i = H, L} U_P = \lambda \phi_H [\pi_H q_H (v - \theta_H) + (1 - \pi_H) C_H - B_H] +$$

$$\lambda \phi_H [\pi_L q_L (v - \theta_L) + (1 - \pi_L) C_L - B_L] -$$

$$\lambda \phi_H [\pi_H q_H \Delta \theta - (1 - \pi_H) \Delta C + \Delta B]$$

\(^4\)For completeness, in the Appendix, we state the main results for the case in which the parameter values are such that high types have incentives to understated their type and mimic low cost types. These two cases arise because of the existence of the type-dependent ex ante outside options, $B_1$, as has been analyzed in detail by Maggi and Rodriguez-Clare (1995). Note that in the knife-edge case where $\overline{q} \Delta \theta + \Delta B = 0$ the principal can offer the full information contract to both types without inducing either to mimic the other, so this is clearly her favored course of action.
subject to \( \phi_H [\pi_H q_H \Delta \theta - (1 - \pi_H) \Delta C + \Delta B] \geq 0 \). \hfill (C1)

where (C1) derives from Lemma 1. We first solve (P) ignoring (C1). If the solution satisfies (C1) with strict inequality, it is the solution to the overall problem. Otherwise (C1) binds.

The principal faces a standard trade-off between efficiency and informational rents. If she offers \( \theta_H \) types the efficient (full-information) contract where \( \phi_H = \pi_H = 1, q_H = \bar{q} \), then she must also offer positive rents to \( \theta_L \) types to prevent mimicking. In this case (C1) is slack. If the principal wishes to eliminate \( \theta_L \)'s rents, then she must distort type \( \theta_H \)'s contract away from the efficient contract.\(^5\) In this case (C1) binds so, conditional on \( \phi_H = 1 \), we have,

\[
q_H = \frac{(1 - \pi_H) \Delta C - \Delta B}{\pi_H \Delta \theta}. \tag{3}
\]

When \( \Delta C - \Delta B > 0 \) – i.e., the opportunity cost of randomization is higher for \( \theta_L \) than for \( \theta_H \) – then (3) implies that \( \partial q_H / \partial \pi_H < 0 \). By lowering \( \pi_H \) the principal can increase \( q_H \) whilst keeping \( \theta_L \)'s rents at zero. A trade-off then emerges. A lower \( \pi_H \) decreases the probability of trade, but it also increases \( q_H \), and hence the value of trade. When the latter effect is stronger than the former, the optimal contract (conditional on C1 binding) prescribes \( q_H = \bar{q} \) and \( \pi_H = (\Delta C - \Delta B) / (\bar{q} \Delta \theta + \Delta C) \in (0, 1) \), i.e. it prescribes randomization.\(^6\) Proposition 1 fully describes the optimal second best contracts.\(^7\)

**Proposition 1:** For type \( \theta_L \), the optimal contract always prescribes \( \phi_L = \pi_L = 1, q_L = \bar{q} \). If

\[
\lambda > \max \left\{ \frac{\Delta C + \bar{q} \Delta \theta}{\bar{q}(v - \theta_L) - C_L}, \frac{\Delta \theta}{v - \theta_L}, \frac{\Delta B + \bar{q} \Delta \theta}{\bar{q}(v - \theta_L) - B_L} \right\}, \tag{4}
\]

then (C1) is slack, and the optimal contract for type \( \theta_H \) has \( \phi_H = \pi_H = 1, q_H = \bar{q} \). If (4) does not hold, then (C1) binds, and the optimal contract for type \( \theta_H \) is

(i) if \( C_H > \frac{C_L(v - \theta_H)}{v - \theta_L} \) and \( \Delta C - \Delta B > \frac{(B_H - C_H)(\bar{q} \Delta \theta + \Delta C)}{\bar{q}(v - \theta_H) - C_H} > 0 \): \( \phi_H = 1, \pi_H = \frac{\Delta C - \Delta B}{\bar{q} \Delta \theta + \Delta C} \) and \( q_H = \bar{q} \).

(ii) if \( C_H < \frac{C_L(v - \theta_H)}{v - \theta_L} \) and \( \Delta B < -\frac{B_H \Delta \theta}{v - \theta_H} < 0 \): \( \phi_H = \pi_H = 1 \) and \( q_H = -\frac{\Delta B}{\Delta \theta} \).

(iii) in all the other cases: \( \phi_H = 0 \).

If \( \text{prob}(\theta = \theta_H) = \lambda \) is sufficiently high, then the principal finds it optimal to offer \( \theta_H \) types the efficient contract, so as to maximize her profit when trading with \( \theta_H \) types, even if this implies that positive rents are relinquished to agents of type \( \theta_L \). Conversely, if \( \lambda \) is sufficiently low, then the principal prefers to allow (C1) to bind and so eliminate any rents to \( \theta_L \) types.

Proposition 1 shows that in order for the optimal contract for \( \theta_H \) to prescribe randomization, \( \Delta C - \Delta B \) should be positive, and sufficiently large. Intuitively, \( \Delta C - \Delta B > 0 \) implies that the opportunity cost of randomization is higher for \( \theta_L \) types than for \( \theta_H \). Hence, by offering \( \theta_H \) types a contract involving randomization, the principal can lower the incentives of \( \theta_L \) types to overstate their costs and mimic \( \theta_H \) types. By contrast, if \( \Delta C - \Delta B < 0 \), then \( \theta_H \) types stand to lose more from randomization than \( \theta_L \) types, and so randomization would not help deter \( \theta_L \) from mimicking \( \theta_H \). Similarly, if \( \Delta C = \Delta B = 0 \) – as is the case if both ex ante and ex post outside options are type-invariant so \( B_H = B_L \) and \( C_H = C_L \) – then the opportunity cost of randomization is the same for both types, and again randomization is not an

\(^5\)Given the linearity of her payoff, the principal would never select contracts between these extremes.

\(^6\)That \( (\Delta C - \Delta B) / (\bar{q} \Delta \theta + \Delta C) \in (0, 1) \) follows from \( \Delta C - \Delta B > 0 \) and assumption A1.

\(^7\)We adopt the convention that if \( P \) is indifferent between setting \( \phi_i = 1 \) or \( \phi_i = 0 \) for \( i = H, L \), then she selects \( \phi_i = 0 \). Similarly, if she is indifferent between all \( \pi_i \in [0, 1] \) (resp., all \( q_i \in [0, \bar{q}] \)) then \( P \) selects \( \pi_i = 0 \) (resp., \( q_i = 0 \)).
effective screening tool. This clarifies why type-dependent outside options are essential for randomization to be optimal.

Note that, in order for randomization to be optimal, $\Delta C - \Delta B$ should not only be positive, but also sufficiently large. This ensures that a small amount of randomization in the contract offered to $\theta_H$ is sufficient to deter $\theta_L$ from mimicking, and guarantees that the principal can obtain a positive expected profit when trading with type $\theta_H$.

What are the implications of $\Delta C - \Delta B > 0$? From (3), we know that when (C1) binds and $\Delta C - \Delta B > 0$ then a trade-off emerges between $\pi_H$ and $q_H$. A lower $\pi_H$ decreases the probability of trade, but it also increases $q_H$, and hence the value of trade. For randomization to be optimal, the principal must then be willing to lower the probability of trade with $\theta_H$ in order to raise $q_H$ at the margin. Whether this occurs or not, depends on the precise comparison between the costs (i.e., trade with $\theta_H$ occurs less often) and the benefits (i.e., $q_H$ is higher) of randomization.

To see how the former may outweigh the latter, consider the simple case where $C_L < C_H < 0$, $B_H = B_L = 0$. Since *ex ante* outside options are independent of type, if $\pi_H = 1$, this case corresponds to the canonical model. As can be seen from (C1), leaving no rents to type $\theta_L$ then requires $q_H = 0$. The principal’s payoff when dealing with type $\theta_H$ is then equal to zero. By contrast, setting $\pi_H < 1$ allows the principal to set $q_H = (1 - \pi_H) \Delta C/\pi_H \Delta \theta > 0$. Here, the cost of imposing randomization is null, since when $\pi_H = 1$ trading with type $\theta_H$ generates no profits (this follows from $q_H = 0$). By contrast, if $C_H$ is not too negative, i.e. $C_H > C_L(v - \theta_H)/(v - \theta_L)$, then the benefit of randomization is strictly positive, since it allows the principal to obtain a strictly positive expected payoff when dealing with $\theta_H$.

Conditional on the principal wishing to leave no rents to type $\theta_L$ (which, as highlighted by proposition 1, happens whenever $\lambda$ is sufficiently low), randomization is then clearly optimal. Given the linearity of her payoff, if the principal finds it optimal to sacrifice $\pi_H$ in order to raise $q_H$ at the margin, then she goes all the way, and sets $q_H$ as high as possible in the optimal contract, i.e. $q_H = \bar{q}$. From (3), $\pi_H$ is then equal to $(\Delta C - \Delta B)/ (\bar{q} \Delta \theta + \Delta C)$.

**A Numerical Example** In the Appendix, we discuss a numerical example where $\theta_H = 0.75$, $\theta_L = 0.25$, $\bar{q} = v = 2$, and the agent’s *ex ante* and *ex post* outside options are $B_H = 1.85$, $B_L = 2.35$, $C_H = 1.75$, and $C_L = 1.95$. In that case, it is straightforward to show that, for $\lambda < 0.52$, the optimal contract offered to type $\theta_H$ prescribes $\phi_H = 1$, $\pi_H = 0.375$ and $q_H = \bar{q} = 2$.

### 4 Discussion

**Efficiency** Proposition 1 highlights the impact of having *two* (i.e., *ex ante* and *ex post*) type-dependent outside options on the optimal second best contracts. Suppose that, on the contrary, $C_i = B_i$ for both $i = H, L$, so $\Delta C = \Delta B$. From (3), the only way for (C1) to then bind is to set $q_H = -\Delta B/\Delta \theta$. If (4) does not hold and $\Delta B \geq -B_H \Delta \theta / (v - \theta_H)$, then the optimal contract prescribes $\phi_H = 0$, i.e. no trade between the principal and agents of type $\theta_H$, since with $q_H = -\Delta B/\Delta \theta$ the principal would never

---

Footnote:

8The principal’s expected payoff from dealing with $\theta_H$ when $q_H = (1 - \pi_H) \Delta C/\pi_H \Delta \theta$ is equal to $(1 - \pi_H) [C_H(v - \theta_L) - C_L(v - \theta_H)] / \Delta \theta - B_H$. In this simple example, $B_H = 0$. The condition $C_H > C_L(v - \theta_H)/(v - \theta_L)$ is therefore both necessary and sufficient to ensure that randomization is optimal whenever (C1) binds. More generally, this requirement is only necessary (as highlighted in part (i) of proposition 1, another condition is also required). Intuitively, if $C_H$ is very low, then the transfer necessary to induce type $\theta_H$ to accept a contract involving randomization would be large, and randomization would therefore not be optimal.
obtain a non-negative profit when dealing with type \( \theta_H \). In contrast when \( B_i \neq C_i \), trade between the principal and agents of type \( \theta_H \) may occur with positive probability even if \( \Delta B \geq -B_H \Delta \theta / (v - \theta_H) \).

Hence, in a complete contracting environment, the need for agents to undertake relationship-specific investments \( \text{ex ante} \) that decrease the agent’s outside option, can result in greater \( \text{ex post} \) efficiency, that is, at the production stage. This is because such investments enable the principal to utilize randomization as a tool to screen between agent types. To our knowledge, the earlier literature has not noted this potentially useful role for \( \text{ex ante} \) relationship-specific investments to improve on \( \text{ex post} \) efficiency. The literature has emphasized rather, that in the presence of contractual incompleteness, investment specificity results in \( \text{ex ante} \) inefficiencies, i.e. inefficiencies at the investment stage (Grout 1984, Grossman and Hart 1986, Hart and Moore 1990).

### Relaxing the Linearity Assumption

The restriction to linear payoff functions allows us to abstract from risk-aversion considerations, and to differentiate our results from the existing literature on randomization in mechanism design (Stiglitz 1982, Arnott and Stiglitz 1988, Brito et al 1995). However, our results extend also to non-linear settings. To see this, suppose agents face convex production costs, so the net utility of an type \( \theta_i \) agent when accepting a contract \( \{\phi, \pi, q, T\} \) is,

\[
T + \phi \left[ -\pi \theta_i g(q) + (1 - \pi)C_i - B_i \right].
\]

(5)

where \( g'(q) > 0 \) and \( g''(q) > 0 \) for all \( q > 0 \). Suppose that, if offered the full-information contract, a type \( \theta_L \) agent would overstate his cost and mimic type \( \theta_H \), as was the case throughout Section 3. Condition (C1) then is,

\[
\phi_H \left[ \pi_H g(q_H) \Delta \theta - (1 - \pi_H) \Delta C + \Delta B \right] \geq 0.
\]

(C1’)

Following the same argument as in Proposition 1, for \( \lambda \) sufficiently low, the optimal contract for type \( \theta_H \) agents is such that (C1’ binds. Then, conditional on \( \phi_H = 1 \), we have,

\[
q_H = g^{-1}\left( \frac{(1 - \pi_H) \Delta C - \Delta B}{\pi_H \Delta \theta} \right).
\]

(6)

As in the linear case, when \( \Delta C - \Delta B > 0 \), (6) implies that \( \partial q_H / \partial \pi_H < 0 \), so that, by lowering \( \pi_H \), the principal can increase \( q_H \). Clearly, this is a necessary requirement for randomization to be offered, or else the principal would always optimally select \( \pi_H = 1 \). Note that, in contrast with the linear case above, in this non-linear case the trade-off between \( \pi_H \) and \( q_H \) may actually make \( U_P \) concave in \( \pi_H \) – thus warranting randomization even in the absence of restrictions on feasible output quantities. To see this, let \( g(q) = 0.5q^2 \), and suppose that parameter values continue to follow the numerical example given above, but the restriction that \( q \) may not exceed \( \bar{q} \) is relaxed.

Expression (6) then becomes \( q_H = \sqrt{0.8 + \frac{1.2}{\pi_H}} \). Conditional on \( \phi_H = 1 \), the principal’s expected payoff when dealing with a type \( \theta_H \) agent is \( U_P = \pi_H \left[ 2 \sqrt{0.8 + \frac{1.2}{\pi_H}} - 0.75 \left( 0.4 + \frac{0.6}{\pi_H} \right) - 1.75 \right] - 0.1 \), which is concave in \( \pi_H \). The optimal contract for \( \theta_H \) is \( \phi_H = 1 \), \( \pi_H = 0.78 \), and \( q_H = 1.53 \), and when dealing with type \( \theta_H \), the principal’s expected profit is 0.23. Hence in this numerical example, for \( \lambda \) sufficiently low the optimal contract for \( \theta_H \) may again prescribe randomization, although in contrast with the linear case, the optimal \( q_H \) is below its first-best value.

\[ ^9 \text{This is the case for instance in the numerical example introduced above, where } \Delta B = -0.5 > -B_H \Delta \theta / (v - \theta_H) = -0.74. \]
Allowing for Randomization Over $\phi$  What would happen if instead of assuming $\phi \in \{0,1\}$, $\phi$ were allowed to take any value in $[0,1]$? In that case, randomization over $\phi_H$ would be possible. However, we argue that it would not be optimal.\footnote{It is straightforward to see that in our framework randomization over $\phi_L$ is also never optimal.} To see why, note that, similar to what happens for randomization over $\pi_H$, randomization over $\phi_H$ may only be optimal when (C1) binds $-\phi_H$ enters the principal’s payoff linearly, so if (C1) is slack then $\phi_H$ optimally takes a corner value. Consider now a contract $M_H = \{\phi_H, \pi_H, q_H, u_H\}$, where $\phi_H \in (0,1)$ and $u_H = 0$ (as discussed above, this latter condition is always satisfied at an optimum). Under this contract, the opportunity cost of randomization over $\phi_H$ for an agent of type $\theta_i$ is equal to $-\theta_i \pi_H q_H + (1 - \pi_H)C_i - B_i$, namely the expected net payoff that the agent obtains when he undertakes the relationship-specific investment.\footnote{Recall that in our framework the relationship-specific investment is necessary for trade between the principal and the agent to occur. Given a contract $\{\phi, \pi, q, T\}$ if the agent undertakes the relationship-specific investment, his expected utility is $T - \theta_i \pi q + (1 - \pi)C_i$, while if the agent does not undertake the relationship-specific investment, his utility is $T + B_i$.} Following the same logic as in the case of randomization over $\pi_H$, if this opportunity cost differs between types, then this may provide a possible rationale for randomization over $\phi_H$ to be optimal. However, if (C1) binds, then the net payoff that the agent obtains when he undertakes the relationship-specific investment under contract $M_H$ is zero for both $\theta_L$ and $\theta_H$.\footnote{This follows since, when (C1) binds, then $-\pi_H q_H \theta_L + (1 - \pi_H)C_L - B_L = -\pi_H q_H \theta_H + (1 - \pi_H)C_H - B_H = 0$.} Hence, the opportunity cost of randomization over $\phi_H$ is equal (and null) for both types. Randomization over $\phi_H$ is therefore ineffective for screening between types.

5 Appendix

5.1 Proofs

Proof of Lemma 1: We show that any menu of contracts in which $\phi_H = 1$ and (2) holds is necessarily dominated, as $P$ could offer a menu that, whilst violating (2), satisfies both $IC_H$ and $IC_L$ and yields him a strictly higher expected payoff. Consider a menu $M = \{M_H, M_L\} = \{(\phi_H, \pi_H, q_H, u_H), (\phi_L, \pi_L, q_L, u_L)\}$ such that $\phi_H = 1$ and (2) holds. $P$’s expected payoff from $M$ is,

$$\lambda \{\pi_H [q_H (v - \theta_H) - C_H] + C_H - B_H - u_H\} + (1 - \lambda) \phi_L \{\pi_L [q_L (v - \theta_L) - C_L] + C_L - B_L - u_L\}. \quad (7)$$

Now consider an alternative menu $\widehat{M} = \{\widehat{M}_H, \widehat{M}_L\}$, where $\widehat{M}_H = (1, \widehat{\pi}_H, \widehat{q}_H, 0)$ and $\widehat{M}_L = (1, 1, \overline{\pi}, 0)$. Under A1, $\widehat{M}$ satisfies $IC_H$. It also satisfies $IC_L$ provided,

$$\widehat{\pi}_H \widehat{q}_H \Delta \theta - (1 - \widehat{\pi}_H) \Delta C + \Delta B \leq 0 \quad (8)$$

We now show that there exist values of $\widehat{\pi}_H$ and $\widehat{q}_H$ which satisfy (8) with equality (i.e., violate (2)) and which are such that $\widehat{M}$ yields $P$ a greater expected payoff than $M$. $P$’s expected payoff from $\widehat{M}$ is,

$$\lambda \{\widehat{\pi}_H [\widehat{q}_H (v - \theta_H) - C_H] + C_H - B_H\} + (1 - \lambda) [\overline{\pi} (v - \theta_L) - B_L]. \quad (9)$$

A sufficient condition for (9) to exceed (7) is,

$$\widehat{\pi}_H [\widehat{q}_H (v - \theta_H) - C_H] - \pi_H [q_H (v - \theta_H) - C_H] > 0. \quad (10)$$
Condition (10) ensures that $P$ prefers $\hat{M}$ to $M$. We distinguish between two cases. First, suppose that $(1 - \pi_H)\frac{\Delta C - \Delta B}{\pi_H \Delta \theta} \leq \eta$. Hence setting $\hat{\pi}_H = \pi_H$ and $\hat{q}_H = \frac{(1 - \pi_H)\Delta C - \Delta B}{\pi_H \Delta \theta}$ ensures (8) holds with equality. Contract $\hat{M}_H = (1, \pi_H, \frac{(1 - \pi_H)\Delta C - \Delta B}{\pi_H \Delta \theta}, 0)$ is feasible because, if (2) holds, then $q_H < \frac{(1 - \pi_H)\Delta C - \Delta B}{\pi_H \Delta \theta}$, which implies $(1 - \pi_H)\Delta C - \Delta B > 0$. With $\hat{\pi}_H = \pi_H$ the LHS of (10) is $\pi_H (\hat{q}_H - q_H) (v - \theta_H)$, which is strictly positive. Hence, $\hat{M}_H$ dominates $M_H$ and so $\hat{M}$ dominates $M$.

Second, suppose $\frac{(1 - \pi_H)\Delta C - \Delta B}{\pi_H \Delta \theta} > \eta$. Note that since $\eta \Delta \theta + \Delta B > 0$ under A1, $-\frac{\Delta B}{\Delta \theta} < \eta < \frac{(1 - \pi_H)\Delta C - \Delta B}{\pi_H \Delta \theta}$, so $\Delta C - \Delta B > 0$. There are then two possibilities to consider.

In the first case, $q_H \Delta \theta + \Delta C > 0$. Inequality (2) can be rewritten as $\pi_H < \frac{\Delta C - \Delta B}{\eta \Delta \theta + \Delta C}$. By setting $\hat{\pi}_H = \frac{\Delta C - \Delta B}{\eta \Delta \theta + \Delta C}$, $\hat{q}_H = q_H$ we ensure (8) holds with equality. The LHS of (10) becomes $(\hat{\pi}_H - \pi_H) [q_H (v - \theta_H) - C_H]$, which is strictly positive. Hence, $\hat{M}_H = \left(1, 1, \frac{\Delta C - \Delta B}{\pi_H \Delta \theta}, q_H, 0 \right)$ dominates $M_H$ and so $\hat{M}$ dominates $M$.

In the second case, $q_H \Delta \theta + \Delta C \leq 0$. For this to hold, we require $\Delta C < 0$. As $\Delta C - \Delta B > 0$, this implies $\Delta B < 0$. By setting $\hat{\pi}_H = 1, \hat{q}_H = -\frac{\Delta B}{\Delta \theta}$ we ensure (8) holds with equality. The LHS of (10) becomes $[-\frac{\Delta B}{\Delta \theta} (v - \theta_H) - C_H] - \pi_H [q_H (v - \theta_H) - C_H]$. Under (2), a sufficient condition for this to be positive is that,

$$C_H (v - \theta_L) - C_L (v - \theta_H) < 0.$$  \hfill (11)

Note however that as $q_H \Delta \theta + \Delta C \leq 0$ in this second case, if (11) does not hold then contract $M_H$ is dominated by a contract that sets $\phi_H = 0$. To see this, note that, by setting $\phi_H = 1$, the extra profit obtained by the principal is non-negative only if $q_H \geq \frac{u_H + B_H - C_H (1 - \pi_H)}{(v - \theta_H) \pi_H}$. For this to be consistent with $q_H \Delta \theta + \Delta C \leq 0$ it is necessarily required that $\frac{B_H - C_H (1 - \pi_H)}{(v - \theta_H) \pi_H} \leq -\frac{\Delta C}{\Delta \theta}$. In turn, this requires $C_H (v - \theta_L) - C_L (v - \theta_H) < 0$. We therefore conclude that contract $M$ is surely dominated.

**Proof of Proposition 1:** We divide the proof in two parts. We first consider the case where (C1) is slack in the optimal contract. We then consider the case where (C1) binds in the optimal contract. First consider the solution of (P) ignoring (C1). It is straightforward to see the optimal $M_L$ prescribes $\phi_L = \pi_L = 1, q_L = \eta$. Consider now the optimal $M_H$.

**Lemma 2:** If condition (C1) is slack in the optimal contract, then the optimal $M_H$ prescribes $\pi_H = \phi_H = 1, q_H = \eta$. Consider now the optimal $M_H$.

**Proof of Lemma 2:** Ignoring (C1), the FOCs for $M_H$ are,

$$\frac{\partial U_P}{\partial \pi_H} = \phi_H q_H [\lambda (v - \theta_H) - (1 - \lambda) \Delta \theta] - \phi_H [\lambda C_H + (1 - \lambda) \Delta C]$$ \hfill (12)

$$\frac{\partial U_P}{\partial q_H} = \phi_H \pi_H [\lambda (v - \theta_H) - (1 - \lambda) \Delta \theta]$$ \hfill (13)

$$\frac{\partial U_P}{\partial \phi_H} = \lambda [\pi_H q_H (v - \theta_H) + (1 - \pi_H) C_H - B_H] - (1 - \lambda) [\pi_H q_H \Delta \theta - (1 - \pi_H) \Delta C + \Delta B]$$ \hfill (14)

For condition (C1) to be slack, it is necessary that $\phi_H = 1$. Hence, the LHS of (14) must be positive.\(^{13}\) This has implications for the optimal values of $\pi_H$ and $q_H$. If the optimal $\pi_H$ in the unconstrained problem is zero, to then have $\phi_H = 1$ requires $\lambda (C_H - B_H) - (1 - \lambda) (\Delta B - \Delta C) > 0$. Since $C_H - B_H < 0$, a necessary condition for this is $\Delta B - \Delta C < 0$. However, when $\phi_H = 1$ and $\pi_H = 0$, this requirement would contradict (C1). Similarly, if the optimal $q_H$ in the unconstrained problem is zero, to then have $\phi_H = 1$ requires $\lambda [(1 - \pi_H) C_H - B_H] - (1 - \lambda) [\Delta B - (1 - \pi_H) \Delta C] > 0$. For this to hold it is necessary that $\Delta B - (1 - \pi_H) \Delta C < 0$. However, when $\phi_H = 1$ and $q_H = 0$, this requirement would again contradict (C1). Hence, if (C1) is slack in the optimal contract, then the optimal $\pi_H$ and the optimal $q_H$ must

\(^{13}\) Recall that, as mentioned in footnote 7, if indifferent between $\phi_H = 1$ and $\phi_H = 0$, $P$ will select $\phi_H = 0$. 

both be strictly positive. As mentioned earlier, we adopt the convention that, if indifferent between all possible values of $q_H \in [0, \bar{q}]$, the principal will select $q_H = 0$, and, similarly, if indifferent between all possible values of $\pi_H \in [0, 1]$, the principal will select $\pi_H = 0$. Since, as proved above, $q_H = 0$ and/or $\pi_H = 0$ are not consistent with $\phi_H = 1$, we conclude that if (C1) is slack in the optimal contract, then the optimal $q_H$ must be $= \bar{q}$, and the optimal $\pi_H$ must be $= 1$.

When $\pi_H = \phi_H = 1$, $q_H = \bar{q}$, (C1) becomes $7Q \Delta \theta + \Delta B \geq 0$, which is satisfied with strict inequality by A1. It remains to verify consistency; given $\pi_H = \phi_H = 1$, $q_H = \bar{q}$, the LHS of (12), (13) and (14) must be strictly positive, to ensure that $\pi_H = \phi_H = 1$, $q_H = \bar{q}$ is indeed optimal. It is straightforward to show that this happens whenever,

$$\lambda > \max \left\{ \frac{\Delta C + \bar{q} \Delta \theta}{\bar{q} (v - \theta_L) - C_L}, \frac{\Delta \theta}{v - \theta_L}, \frac{\Delta B + \bar{q} \Delta \theta}{\bar{q} (v - \theta_L) - B_L} \right\}. \tag{4}$$

Hence, when (4) holds, the optimal contracts prescribe $\pi_i = \phi_i = 1$, $q_i = \bar{q}$ for both $i = L, H$. Moreover, $u_H = 0$, while $u_L = \bar{q} \Delta \theta + \Delta B$ (it is straightforward to check that this satisfies $IC_H$). Condition (C1) is slack. This establishes the first part of the proof of proposition 1.

Second part: When (C1) binds, $q_H = \frac{(1 - \pi_H) \Delta C - \Delta B}{\pi_H \Delta \theta}$, and $P$’s expected payoff is,

$$U_P = \lambda \phi_H \left[ \pi_H \left( \frac{(1 - \pi_H) \Delta C - \Delta B}{\pi_H \Delta \theta} (v - \theta_H) - C_H \right) + C_H - B_H \right] + (1 - \lambda) \phi_L \left[ \pi_L \Delta q_L (v - \theta_L) + (1 - \pi_L) C_L - B_L \right]. \tag{15}$$

It is straightforward to see the optimal $M_L$ in this case also prescribes $\phi_L = \pi_L = 1$, $q_L = \bar{q}$. The optimal $M_H$ maximizes (15) subject to $q_H \in [0, \bar{q}]$. The FOCs are,

$$\frac{\partial U_P}{\partial \pi_H} = \lambda \phi_H \left( \frac{-\Delta C (v - \theta_H)}{\pi_H \Delta \theta} - C_H \right) = \lambda \phi_H \left[ C_L (v - \theta_H) - C_H (v - \theta_L) \right] \tag{16}$$

$$\frac{\partial U_P}{\partial \phi_H} = \lambda \left[ \pi_H \left( \frac{(1 - \pi_H) \Delta C - \Delta B}{\pi_H \Delta \theta} (v - \theta_H) - C_H \right) + C_H - B_H \right] \tag{17}$$

Two cases can arise.\footnote{More precisely, $q_H = \frac{(1 - \pi_H) \Delta C - \Delta B}{\pi_H \Delta \theta}$ must necessarily hold if $\phi_H = 1$ and (C1) binds. If $\phi_H = 0$, then clearly the value of $q_H$ is irrelevant. The expression (15) captures $P$’s expected payoff in both cases.}

In the first case $C_L (v - \theta_H) - C_H (v - \theta_L) < 0$, so conditional on $\phi_H = 1$, $\frac{\partial U_P}{\partial \pi_H} < 0$ and $P$ sets $\pi_H$ as low as possible. If $\Delta C > \Delta B$ then $\frac{\partial U_P}{\partial \pi_H} < 0$ and the lowest feasible $\pi_H$ solves $\bar{q} = \frac{(1 - \pi_H) \Delta C - \Delta B}{\Delta \theta}$, so $\pi_H = \frac{\Delta C - \Delta B}{\Delta \theta}$. Provided $\frac{\Delta C - \Delta B}{\Delta \theta} (\bar{q} (v - \theta_H) - C_H) + C_H - B_H > 0$, the optimal $\phi_H$ is 1. If $\Delta C < \Delta B$ then $\frac{\partial U_P}{\partial \pi_H} > 0$ and the lowest feasible $\pi_H$ solves $q_H = 0$. Similarly, if $\Delta C = \Delta B$ then when $\phi_H = 1$ (C1) may only bind if $q_H = 0$. However, $\phi_H = 0$ is preferred by $P$ in this case, since it allows $P$ to avoid having to pay a positive transfer (namely, $B_H - (1 - \pi_H) C_H$) to type $\theta_H$ to induce his participation.

In the second case, $C_L (v - \theta_H) - C_H (v - \theta_L) > 0$, so conditional on $\phi_H = 1$, $\frac{\partial U_P}{\partial \pi_H} > 0$ and $P$ sets $\pi_H$ as high as possible. If $\Delta B < 0$, then $\pi_H = 1$ and $q_H = \frac{-\Delta B}{\Delta \theta}$. Provided $-\frac{\Delta B (v - \theta_H) - B_H}{\Delta \theta} > 0$, it is then optimal to set $\phi_H = 1$. If $\Delta B > 0$, it is then optimal to set $\phi_H = 0$ as this is the only way to ensure (C1) binds. To see this, note that we can only be in the case $C_L (v - \theta_H) - C_H (v - \theta_L) > 0$ if $\Delta C < 0$ so that, if $\Delta B > 0$, then $\Delta C < \Delta B$. This implies $\frac{(1 - \pi_H) \Delta C - \Delta B}{\pi_H \Delta \theta} < 0$ for all $\pi_H$, and therefore (C1) never binds unless $\phi_H = 0$. Similarly, if $\Delta B = 0$, then when $\phi_H = 1$ (C1) may only bind if $q_H = 0$. However,
as argued above, $\phi_H = 0$ is then preferred by $P$. To complete the description of the optimal contracts, note that when (C1) binds the optimal contracts prescribe $u_H = u_L = 0$. It is straightforward to check $IC_H$ is satisfied in all the cases we have identified.

5.2 Assumption A1 Does Not Hold

For completeness, we consider the case in which $0 \geq \theta H + B$ and so $\theta H$ types have incentives to understate their costs and mimic $\theta L$ types. The remaining assumption A2 is assumed to still hold. The counterparts for the main results are as follows,

Lemma 1B: It is never optimal for the principal to offer $\phi = 1$ in conjunction with $\pi L$ and $q L$ satisfying,

$$-\pi L q L \Delta \theta + (1 - \pi L) \Delta C - \Delta B < 0.$$  \hfill (18)

An implication is that the participation constraint of type $\theta H$ will not bind at the optimum. The optimal contracts are now found by letting $IC H$ hold with equality, setting $u_L = 0$, and ignoring $IC L$. The counterpart to (C1) is,

$$\phi \left[ -\pi L q L \Delta \theta + (1 - \pi L) \Delta C - \Delta B \right] \geq 0.$$ \hfill (C1B)

Proposition 2B: For type $\theta H$, the optimal contract always prescribes $\phi = \pi H = 1$, $q = \theta$. If

$$\lambda < \min \left\{ \frac{\theta (v - \theta L) - C L}{\theta (v - \theta H) - C H}, \frac{\theta (v - \theta L) - B L}{\theta (v - \theta H) - B H} \right\}$$ \hfill (19)

then (C1B) is slack, and the optimal contract for type $\theta L$ has $\phi = \pi L = 1$, $q = \theta$. If (19) doesn’t hold, then (C1B) binds, and the optimal contract for type $\theta L$ is,

(i) if $C H < \frac{C L (v - \theta H)}{\theta L - \theta L}$ and $\Delta C - \Delta B < \frac{(B L - C L)(\Delta \theta + \Delta C)}{\theta L - \theta L} < 0$: $\phi = 1$, $\pi L = \frac{\Delta C - \Delta B}{\Delta \theta}$ and $q = \theta$.

(ii) if $C H > \frac{C L (v - \theta H)}{\theta L - \theta L}$ and $\Delta B < -\frac{B L \Delta \theta}{\theta L - \theta L} < 0$: $\phi = \pi L = 1$ and $q = -\frac{\Delta B}{\Delta \theta}$.

(iii) in all the other cases: $\phi = 0$.

5.3 A Numerical Example

Suppose $\theta H = 0.75$, $\theta L = 0.25$, $\theta = v = 2$, and agent’s ex ante and ex post outside options are $B H = 1.85$, $B L = 2.35$, $C H = 1.75$, and $C L = 1.95$. For (4) to hold we require $\lambda \geq 0.52$. If $\lambda < 0.52$, then (C1) must bind in the optimal contract. From (3), if $\phi = 1$ this implies $q H = \frac{2}{\theta L} + \frac{3}{\theta L}$, and to ensure $q H \leq \theta = 2$, we require $\pi H \geq 0.375$. Conditional on $\phi = 1$, the principal then selects $\pi H \in [0.375, 1]$ to maximize her expected payoff when dealing with a type $\theta H$ agent, $U P = \pi H \left[ \frac{2}{5} + \frac{3}{\theta L} \right] 1.25 - 1.75 - 0.1$. Since $U P$ is decreasing in $\pi H$, so the principal selects the lowest $\pi H$ compatible with (C1). The optimal contract for $\theta H$ then is, $\phi = 1, \pi H = 0.375, q H = \theta = 2$, and when dealing with type $\theta H$ agents, the principal’s expected payoff is 0.18.
